This is the most common corneal manifestation of congenital or acquired syphilis.<sup>22,26,27</sup> Although spirochetes can invade the fetal cornea, interstitial keratitis is immune mediated. Maternal therapy before the second trimester, or treatment of the infant before the age of 3 months, can prevent interstitial keratitis.<sup>7,26–28</sup>

**Interstitial Keratitis in Congenital Syphilis** This is usually a late finding. Most cases manifest between the ages of 5 and 20 years. Acute IK may be triggered by ocular surface inflammation or following intraocular surgery. It most often affects the deep stromal layers either as multifocal infiltrates or as a diffuse process. Corneal stromal edema may result from the inflammation, resulting in a ground glass cornea. Variable degrees of deep corneal stromal neovascularization may be present, depending on the severity of the inflammation. Typically, the neovascularization begins at the corneal limbus. Stromal inflammation overlying the vessels often causes a salmon colored patch due to the pinkish color imparted by the stromal vessels. Intrastromal hemorrhage may also occur.

Interstitial keratitis may finally result in scarring of the corneal stroma and collagen remodeling. The superficial vessels are reabsorbed and the deeper vessels may be constricted resulting in ghost vessels that are seen as a late finding of syphilitic IK.

**Table 64.3:** Visual Field Defects in Ocular Syphilis

Type of lesion	Type of visual field defect
Syphilitic choroiditis	Ring scotoma
Optic neuritis	Central scotoma
Tabetic optic atrophy	Peripheral constriction with central or cecocentral scotoma or sectoral defect
Syphilitic basilar meningitis	Irregular bitemporal or rarely, binasal hemianopia
Syphilitic arteritis affecting middle cerebral artery	Complete or partial homonymous hemianopia or quadrantanopia

Congenital syphilitic IK is typically bilateral in 80% of cases.<sup>28</sup> Very rarely, both eyes are involved simultaneously. Usually, following inflammation of the first eye, the contralateral eye is affected may be after an interval of as short as 2 months or longer than 15 years.

**Interstitial Keratitis in Acquired Syphilis** Corneal disease in acquired syphilis is rare. Although interstitial keratitis may be seen, it is usually unilateral and may occur relatively early following primary syphilis. The patient presents with pain, photophobia, tearing, and blurred vision, similar to the symptoms seen in acute IK. In general, the symptoms are less severe and of a shorter duration.

The clinical findings of IK in acquired syphilis very closely resemble those seen in IK in congenital syphilis. Late findings include an opacification of the stroma with ghost vessels and thinning. Endothelial changes in the form of redundant basement membrane at the level of Descemet membrane may also be present. Endothelial decompensation may follow, resulting in central corneal edema later in life.<sup>7,25,26</sup>

### Syphilitic Uveitis

Patients with syphilis can present with anterior uveitis, posterior uveitis, or panuveitis.

**Anterior Uveitis** Iridocyclitis in acquired syphilis is typically associated with a skin rash, but sometimes occurs as the only clinical sign in relapsing syphilis. It begins as an acute unilateral iridocyclitis that may be subclinical. The contralateral eye is affected in about 50% of the patients.<sup>7,14</sup> Transient iris roseola, reddish spots, or engorged vascular tufts resembling mucocutaneous lesions may precede the uveitis. Syphilitic uveitis commonly presents as a granulomatous inflammation. It may manifest as iris nodules which are similar in appearance to those seen in other granulomatous diseases. Vascularized nodules or papules at the pupillary border and near the root of the iris may occur during secondary or gummatous tertiary syphilis and lead to sectoral iris atrophy.<sup>28</sup> Iris and ciliary body gummata may also occur.<sup>13</sup> Ciliary body gumma may protrude into the anterior chamber angle as a brownish mass and even penetrate the scleral wall. The severity of the anterior uveitis can vary from a mild iritis to chronic iridocyclitis with hypopyon, anterior vitreous cells and cystoid macular edema.<sup>14,29</sup>

**Posterior Uveitis** A sprinkling of pigmented and depigmented spots (salt and pepper fundus) is a common feature of congenital syphilis. The posterior segment in acquired syphilis can manifest in different forms, such as vasculitis, macular edema, stellate maculopathy, pseudoretinitis pigmentosa, and neuroretinitis.<sup>3,7,14</sup> Other presentations include diffuse chorioretinitis (Fig. 64.5), uveal effusion, central retinal vein occlusion (CRVO), subretinal neovascular membrane formation, and exudative detachment.<sup>14</sup> Necrotizing retinitis can occur and may lead to neovascularization with vitreous hemorrhage or tractional bands between the disc and macula. Gumma of the choroid and retina may also occur. In HIV-infected individuals, large, yellowish placoid lesions

**Fig. 64.5:** Diffuse chorioretinitis in a patient of secondary syphilis.

are seen with atrophic centers with or without hemorrhage in macular or juxtapapillary region which are located at the level of retinal pigment epithelium. Gass, in 1990, coined the term “syphilitic posterior placoid chorioretinitis” when he described 6 patients with secondary syphilis who showed similar types of lesion.<sup>30</sup> The fluorescein angiogram characteristically shows early hypofluorescence and late staining of the lesions, and are often termed as “leopard spot” hypofluorescence.

### DIAGNOSIS OF SYPHILIS

A diagnosis of ocular syphilis is based on a clinical suspicion which can be confirmed by appropriate diagnostic tests. Dark field microscopy involves direct identification of *Treponema pallidum* by examining exudates from a chancre or condyloma latum. In syphilitic infection, there is production of nonspecific antibodies which react to cardiolipin. This forms the basis of traditional nontreponemal tests such as Venereal Disease Research Laboratory (VDRL) tests and rapid plasma reagin tests. On the other hand, the treponemal tests like *Treponema pallidum* particle agglutination (TPPA) detect antibodies against *Treponema pallidum*. The serological tests used for the diagnosis of syphilis are summarized in Fig. 64.6.

The nontreponemal tests show a decline in titres or become nonreactive with treatment, so they can be used to assess the response to treatment. Treponemal tests generally remain reactive

**Fig. 64.6:** Crab louse on the eyelashes along the lid margin.

for life. These tests are associated with a lower incidence of false positivity and they are more specific.

For diagnosis of neurosyphilis, there is no definite test. Although VDRL-CSF is highly specific, it is insensitive. Although, the CSF TPPA is less specific for neurosyphilis than CSF VDRL (i.e., yields more false positive results), it is highly sensitive. As syphilitic uveitis or other ocular involvement is frequently associated with neurosyphilis, a CSF examination needs to be considered for confirmation of diagnosis.<sup>31</sup>

## SYPHILIS AND HIV INFECTION

Concurrent infection of syphilis with HIV has been suggested to be more aggressive than syphilis alone. Syphilis can be rapidly progressive and relapses frequent in HIV-infected patients.<sup>32-34</sup> Ophthalmic manifestations of syphilis may occur during or shortly after the secondary stage (Table 64.4).<sup>35</sup> Anterior uveitis is the most common presentation, but posterior uveitis (panuveitis) also occurs.<sup>36</sup> Ocular syphilis in an HIV-infected patient is often accompanied by neurological involvement. Neuro-ophthalmic syphilis may also be the presenting feature of HIV infection. As in HIV seronegative patients, syphilis can present in HIV-infected patients with a wide variety of ocular manifestations including retinitis, neuroretinitis, optic neuritis, perineuritis, papillitis, retinal detachment, vitritis, and optic nerve gumma. However, ocular complications of syphilis may be more severe and frequent and may develop earlier in HIV-infected individuals.<sup>35-38</sup> Because of syphilis, posterior segment and neuroophthalmic lesions are more common in HIV-infected individuals.

## CLINICAL PEARLS IN OCULAR LESIONS OF SYPHILIS

- Syphilis is a great mimicker. Always keep this condition in mind in patients with cranial neuropathies, optic neuropathies, anterior uveitis, chorioretinitis, retinal vascular occlusion, and chronic anterior segment inflammation.
- Manifestations of syphilis can be complicated by concurrent HIV infection. Always screen patients with syphilis for HIV infection. Further, concurrent infections with gonorrhea and Chlamydia may frequently occur and should be investigated accordingly.
- Nearly 45% of males manifesting bilateral tonic pupils will test positive for syphilis.
- Lyme disease, another spirochetal disease, can mimic syphilis. In fact, Lyme disease can cause false positive specific and

**Table 64.4:** Common Ocular Manifestations of Syphilis in HIV-infected Patients

Anterior segment	Posterior segment	Neuro-ophthalmic
Anterior uveitis	<ul style="list-style-type: none"> <li>• Diffuse vitritis</li> <li>• Posterior uveitis or Panuveitis</li> <li>• Exudative retinal detachment</li> <li>• Necrotising retinitis</li> </ul>	<ul style="list-style-type: none"> <li>• Neuroretinitis</li> <li>• Papillitis</li> <li>• Perineuritis</li> <li>• Retrobulbar neuritis</li> </ul>

nonspecific tests for syphilis. Always consider Lyme disease as a possibility when testing for syphilis, particularly in cases where a history of high-risk sexual behavior is absent. In these cases, particularly in endemic areas, try to elicit a history of tick bite.

- Stromal interstitial keratitis is primarily a manifestation of congenital syphilis, but may occur in acquired syphilis. Interstitial keratitis is treated with high doses of potent topical steroids as this is inflammatory in nature and not actual stromal infection.

## TREATMENT OF OCULAR SYPHILIS

Parenteral penicillin G is the drug of choice for the treatment of all stages of syphilis. Ocular syphilis is a form of neurosyphilis and requires the same therapy. The therapy for ocular syphilis with concurrent HIV infection is the same as that for neurosyphilis in seronegative patients.

## Neisseria Gonorrhoeae and Eye Lesions

Gonorrhea is a major sexually transmitted infection worldwide, although up to 80% of women and 10% of men are asymptomatic.<sup>1</sup> In the newborn, *Neisseria gonorrhoeae* may result in ophthalmia neonatorum (neonatal conjunctivitis). This presents as acute or hyperacute conjunctivitis within the first few days of life. If untreated, it may rapidly progress to corneal ulceration and perforation. Such infection in an immunologically immature child can lead to sepsis and death.<sup>45,46</sup>

The differential diagnosis of neonatal conjunctivitis is given in Table 64.5.

Ocular infection in adults usually results from autoinoculation of the conjunctiva by a person with genital gonorrhea.<sup>48</sup> Gonococcal conjunctivitis is usually severe, with an overtly purulent exudate and the evaluation of any patient with severe purulent conjunctivitis should include a detailed sexual history, genital examination, Gram stain, and culture. In adults, *N. gonorrhoeae* infection presents as a hyperacute, mucopurulent conjunctivitis or keratoconjunctivitis. It progresses rapidly with edema of the eyelid and conjunctiva. Corneal epitheliopathy often occurs due to the toxicity of the discharge. *N. gonorrhoeae* is one of the few organisms that can penetrate the intact corneal

**Table 64.5:** Differential Diagnosis of Neonatal Conjunctivitis

Disease	Onset	Laboratory tests	Treatment
Chemical conjunctivitis	24 hrs	None	Observation
Inclusion conjunctivitis	5–14 days	Mixed cellular reaction in smear	Erythromycin
Gonorrhea	3–5 days	Gram-negative diplococci in smear	Penicillin/ceftriaxone
Neonatal herpes	3–21 days	Positive fluorescent antibody test	Topical and systemic antivirals

epithelium. The patient experiences tenderness and aching of the globe, and palpation reveals a prominent preauricular node. Delays in diagnosis and treatment may result in corneal ulceration and scarring.

### DIAGNOSIS AND MANAGEMENT

The use of culture and sensitivity testing from the primary site of inoculation is essential. Preliminary Gram stains can direct the initial therapy. Gram stain has a high specificity (99%) and sensitivity (>95%) in the diagnosis of gonococcal conjunctivitis. It usually shows polymorphonuclear leucocytes with intracellular gram negative diplococci, but a negative gram stain does not rule out infection with *Neisseria gonorrhoeae*.<sup>31</sup> In the treatment of neonatal conjunctivitis, both topical and systemic therapies should be initiated. Topical aqueous penicillin 10,000 to 20,000 U/mL instilled every hour for first 6 to 12 hours followed by every 2–3 hours till resolution. An alternative treatment is topical tetracycline ointment every 2 hours. Treatment of hyperacute gonococcal infections in adults involves aggressive systemic antibiotic therapy. Ceftriaxone is the drug of choice in treating adult and neonatal gonococcal ophthalmia.<sup>31,42</sup> Spectinomycin is an alternative for patients allergic to ceftriaxone.<sup>43</sup>

### Chlamydia Trachomatis and Eye Lesions

Chlamydia infection is the most common sexually transmitted disease in the developed world.<sup>39,44,45</sup> The organism implicated is *Chlamydia trachomatis* and transmission occurs via direct exposure to infected genital secretions. In the past, poorly chlorinated swimming pools and hot tubs were implicated as well, although this route of infection has been questioned.<sup>39,45</sup>

Neonatal transmission may occur during vaginal delivery. Inclusion conjunctivitis in adults occurs in one out of 100–300 cases of genital chlamydial infection.<sup>46,47</sup> However, more than half of all individuals diagnosed with chlamydial eye disease manifest a concomitant genital infection.<sup>47</sup>

In adults, an acute or subacute follicular conjunctivitis typically ensues after an incubation period of about 5 days. A unilateral or asymmetric presentation is more common. Symptoms may include foreign body sensation, photophobia, redness, lid swelling, and sticky, mucopurulent discharge from the involved eye, which may cause difficulty in opening the eye lids upon awakening.

Slit lamp biomicroscopy reveals moderate injection of the bulbar conjunctiva with variable edema. One may also observe a prominent follicular reaction and, to a lesser extent, papillary hypertrophy. Corneal involvement may occur about 2 weeks after the onset of conjunctivitis in the form of a punctate epithelial keratopathy with or without subepithelial infiltrates. If untreated, vascularization and pannus may ensue. Anterior uveitis may also accompany inclusion conjunctivitis, most commonly in those with a history of collagen vascular disorders. On palpation a nontender preauricular lymphadenopathy on the side of the involved eye is almost always detected.

### DIAGNOSIS AND MANAGEMENT

The diagnosis of inclusion conjunctivitis is based on the clinical presentation, and a history of genital infection and related symptoms.<sup>47</sup> One should suspect chlamydial infection if a chronic follicular conjunctivitis resists topical therapy for some weeks. Various tests are available to diagnose ocular chlamydial infections including culture, direct fluorescent antibody test (DFA), and nucleic acid amplification test.

Systemic antibiotics are the treatment of choice for inclusion conjunctivitis. While topical therapy may ease the ocular symptoms, it will not affect the cure. Azithromycin 1 g orally in a single dose or doxycycline 100 mg orally twice a day for 7 days are the drugs of choice in adults. Erythromycin 50 mg/kg/day orally divided in to four doses daily for 14 days is recommended for Chlamydia ophthalmia in neonates.<sup>31</sup>

### Herpes Simplex Virus (HSV) and Eye Lesions

The virus occurs in two forms: HSV type 1, which has traditionally been implicated in ocular and oral herpes infections; and HSV type 2, which had been considered primarily a cause of genital herpes. Eighty per cent of the neonatal HSV infections are caused by HSV type 2. With changes in sexual behavior, the frequency of the HSV type 1 infections occurring in the genital area has risen since the 1970s.<sup>48</sup>

Human beings are the only natural host of the herpes simplex virus. Transmission typically occurs by direct contact with an open epithelial lesion or contaminated body secretions. Rarely, the virus may spread through contaminated materials such as towels or tissues. As with other STIs, herpes simplex can cause ophthalmia neonatorum due to transmission from an infected mother (neonatal HSV). The features of the neonatal HSV are described in Table 64.6.

In herpetic eye disease secondary to genital infection, the onset typically occurs 1–2 weeks after the eruption of the genital lesions. Symptoms of ocular HSV infection may include photophobia,

**Table 64.6:** Manifestations of Neonatal Ocular HSV

#### Manifestations of neonatal ocular HSV

- Periocular vesicles
- Conjunctivitis
- Keratitis
  - A. Epithelial
  - B. Stromal
- Inflammation
  - A. Anterior uveitis
  - B. Vitritis
- Lenticular opacities (i.e., cataract)
- Retina
  - Vasculitis
  - Retinitis
  - Retinal detachment
  - Chorioretinal scars
  - Exudate
- Optic neuritis

**Table 64.7:** Manifestation of Adult Primary Ocular Herpes Simplex

Constitutional	Ocular diseases

Fever	Conjunctivitis
Myalgias	Epithelial keratitis
Lymphadenopathy	Subepithelial infiltrate
	Interstitial keratitis
	Disciform keratitis
	Uveitis
	Retinitis

epiphora, foreign body sensation, and blurred vision. Clinical signs include follicular conjunctivitis, blepharitis and keratitis. Small vesicles arise on the lid margin and periocular skin, which then ulcerate and produce edema leading to an erosive dermatitis. Conjunctival follicles and punctate keratopathy, with or without subepithelial infiltrates, may follow (Table 64.7).

After the initial infection, the virus lies dormant within the trigeminal, ciliary and/or the superior cervical ganglia. Recurrences of ocular HSV almost invariably strike the cornea, and about 50% of patients get recurrent infections within the first 5 years.<sup>49</sup>

HSV keratitis typically presents as a unilateral red eye, with variable pain or irritation. Photophobia and epiphora are common. Vision may or may not be affected, depending on the location and extent of the corneal lesion. The hallmark of HSV keratitis is a dendritic epithelial lesion. Each recurrent attack augments damage to the corneal nerves, which eventually leads to hypoaesthesia. Following dendritic keratitis, disciform stromal keratitis may develop in some cases. This presents as a central dense area of inflammation and edema surrounded by immune cells, known as a “Wessely ring.” Late complications of recurrent HSV ocular infection may include necrotizing interstitial keratitis, chronic uveitis, and secondary glaucoma.<sup>50</sup>

One of the most visually devastating consequences of posterior segment involvement is acute retinal necrosis. It is a vaso-occlusive angiitis of chorioretinal vessels along with necrotizing retinitis. Acute retinal necrosis typically starts in the periphery and can lead to retinal detachment.

Table 64.7 summarizes the ocular lesions due to herpes simplex.

## DIAGNOSIS AND MANAGEMENT

Primary ocular herpes infection should be suspected in patients with unilateral blepharoconjunctivitis and vesicular lid lesions. Scrapings, blood tests, and detection from the vesicles may help confirm the etiology. Recurrent HSV infection can usually be diagnosed by clinical observation alone, although laboratory tests are required to confirm it. In cases with diagnostic dilemmas, real-time PCR with corneal epithelial scrapping, tear fluid has been found to be useful.

HSV infections are typically self-limiting and usually resolve within 10–14 days. Symptomatic vesicular lid lesions

can be managed with warm compresses. Topical steroids are contraindicated for HSV lid lesions, as they may predispose to corneal involvement.<sup>51</sup>

Recurrent HSV corneal epithelial infections require prompt and aggressive therapy to prevent corneal scarring. The treatment consists of the application of topical trifluridine 1%, up to nine times daily. As the dendritic ulcers regress, medicines are tapered until complete resolution, usually within 7–10 days. After that, the medication should be continued three times daily for another week to ensure complete suppression of the virus. Debridement of the ulcer bed is advocated by some, but there is no proof that this speeds up the resolution or improves the visual outcome. Cycloplegia is indicated for associated uveitis.

Disciform stromal keratitis presents a greater clinical challenge, as it can lead to permanent visual loss. Therapy aims to reduce the inflammation. Cycloplegia is again recommended.<sup>5</sup> In a herpetic eye disease study, it was observed that topical steroids reduced the persistence and progression of stromal inflammation, and shortened the duration of HSV stromal keratitis thereby establishing the benefit of topical corticosteroids in addition to topical antivirals in the treatment of HSV stromal keratitis.<sup>52</sup> Weaker steroids, such as 0.125% prednisolone acetate, or 1% prednisolone sodium phosphate, are preferred. It is advisable to taper the steroids slowly over 10–16 weeks. Concurrent therapy with topical trifluridine, four to five times a day, is essential. Oral acyclovir 400 mg twice a day for 1 year or more has been found useful in prevention of recurrent herpetic disease in patients who have demonstrated a tendency for recurrence.<sup>53</sup>

For the management of neonatal herpetic disease, emergency pediatric or infectious disease consultation should be obtained with reference to initiating immediate intravenous therapy with acyclovir, as there is a definite association between ocular neonatal HSV and potentially lethal systemic or neurological infection. The treatment of focal ocular disease is with topical antivirals in addition to systemic acyclovir regardless of whether the etiologic agent is HSV type 1 or 2. A full ocular antiviral regimen should be instituted immediately. Povidone-iodine gel or ophthalmic bacitracin can be used to minimize the risk of secondary infections.

Treatment of acute retinal necrosis includes prompt initiation of intravenous antiviral medication with acyclovir, in addition to oral steroids to reduce inflammation.<sup>54</sup>

## Crab Louse Infestation

The louse family includes two genera, *Pediculus humanus* and *Phthirus pubis*.<sup>55,56</sup> The most common eyelash infestation is from the pubic louse, and is known as *Phthiriasis pubis palpebrarum*. The pubic crab louse has a predilection for eyelashes and pubic hair because the spacing between the follicles is ideally suited for its grasping apparatus. The most common mode of infestation is hand contact with the genital area. It can also follow orogenital contact. Crab louse infestation presents with pruritic lid margins and blepharoconjunctivitis (Fig. 64.6). Occasionally, preauricular

lymphadenopathy may occur if bites result in a secondary infection. Patients often come with complaints of lid irritation and itching, and it is often misdiagnosed as conjunctivitis. A detailed slit lamp evaluation will reveal crusty, blood-tinged deposits along the lid margins. One may also detect reddish brown fecal matter at the base of the eyelashes.

Diagnosis is confirmed when one observes a louse. One can also usually see white nits, unhatched eggs in the form of oval deposits in the lashes. Reinfestation occurs as the nits hatch following treatment of the adult mites.<sup>57</sup>

## MANAGEMENT

Physical removal of the lice and nits is important, but usually does not totally eradicate the infestation. Supplemental therapy is necessary. Smearing bland petroleum jelly into the lashes in an effort to smother the adult lice or the use of bacitracin ointment, which may also help eradicate a concurrent staphylococcal infection, is useful. Since the nits are immune to this therapy, patients should use the ointment for at least 2 weeks to smother new hatchlings. In addition, use of physostigmine 0.25% (Eserine) ointment will poison the respiratory system of the adult mites. This treatment likewise must extend at least 2 weeks to cover the life cycle of the louse and eradicate the hatchlings.

Alternative ointments for this purpose include yellow mercuric oxide N.F. 1% or ammoniated mercury 3%. Sodium fluorescein used in fluorescein angiography can also be effective. One should keep in mind that the primary infestation involves the genitalia and successful treatment mandates removal of all organisms. Available pediculocides include lotions and shampoos containing g-benzene hexachloride and pyrethrin. A single application is generally sufficient, but reapplication 1 week later will ensure eradication. Because of their toxicity, these pediculocides cannot be used to treat eyelid infestation. Also, given their neurotoxicity, these medications should be used with extreme caution in children and pregnant women.<sup>55-57</sup>

# Arthritis Associated with Sexually Transmitted Infections

Pradeep Bamberg

65

## Introduction

Patients suffering from sexually transmitted infections (STIs) may have acute or chronic joint involvement.<sup>1</sup> Although this may not be a frequent occurrence, severe articular disease can be both incapacitating and deforming. There is a wide clinical spectrum of articular involvement and usually only the severe forms are seen at referral centers. Many more patients have mild joint pain, which is often ignored. Further, some forms of joint involvement may be self-limiting and are thus of less clinical importance.

However, some distinct articular syndromes are associated with STIs, and these are observed fairly regularly and are well-established clinical entities.<sup>1,2</sup> Direct invasion of the joints results in the syndrome of septic arthritis and immune mechanisms triggered by the STI result in an immunologically mediated Sexually Acquired Reactive Arthritis (SARA). Detailed studies of this phenomenon have clearly established a close link between infection and arthritis. As this form of arthritis usually presents acutely, soon after the triggering infection, the interaction between the organism and the host mechanisms is easier to study and establish in this group of conditions than in a disease like rheumatoid arthritis, which is, most often, far more insidious in onset. Several elegant experimental and clinical studies have pieced together a better understanding of the interplay between the host and the pathogen.<sup>3,4</sup> Several animal models, closely mimicking human disease, have also been developed to facilitate research.<sup>3,4</sup>

Among the STIs, gonorrhea, syphilis, chlamydial infections, lymphogranuloma venereum, infection with Human Immunodeficiency Virus (HIV), Hepatitis B Virus (HBV), Hepatitis C virus (HCV), mycoplasma, genital herpes and cytomegalovirus (CMV) have all been implicated in the development of arthritis. Several of these associations have a rich and colorful history.

## History

The relationship between sexual activity and joint diseases was initially recognized by Hippocrates. He proposed that young men

do not get the gout until they are sexually active. At that time all forms of articular disease were referred to as gout. For the next 600 odd years no further developments were recorded. In 300 AD, the development of arthritis following dysentery was noted. As there is close similarity between the development of arthritis following STIs and gastrointestinal tract infections, they will be considered together for the purpose of this historical review.<sup>5-7</sup>

Van Foreest, in 1575, documented the association between urethritis and knee arthritis, and in 1664 Martinere recorded an epidemic of this phenomenon during a military campaign. Seydenham, Morton, and Willis noted this association with arthritis in the great dysentery epidemics between 1668 and 1672. It was, however, Musgrave who noted for the first time in 1715 an association between a venereal disease and arthritis. This relationship was not easily accepted by the medical establishment and John Hunter, in his "Treatise on the Venereal Disease" (2nd ed., 1788), noted that he had never seen "venera attack the joints".<sup>7</sup>

Over the next few years better documentation of observations led to a change in stance. Swediaur, initially in French and later in English, gave a masterly description of knee joint, and later calcaneal swelling after blennorrhagicum. By 1810, the third edition of Hunter's Treatise had changed sufficiently to dub venereal diseases "the seat of rheumatism".<sup>7</sup>

There have been several historical descriptions of arthritis in patients with syphilis and gonorrhea. Gonococcal arthritis was probably first described by Seydenham in 1734 but became an established clinical entity in the later half of the 19th century when Neisser isolated and identified the organism. The relationship of arthritis with syphilis was often mentioned in the older literature. However, with effective treatment and better delineation of other articular syndromes this association is now infrequently reported.

In 1818, Sir Benjamin Brodie described six patients with a symptom complex comprising of urethritis, conjunctivitis, and arthritis. This report predated that of Hans Reiter by almost a century.<sup>6</sup> By 1836, 13 such patients had been recorded and they were recognized to be suffering from a distinct disease entity different from gonococcal arthritis.

In 19th century, two teaching institutions in London recorded that during two different periods of observation arthritis related to STIs comprised roughly 3% of all admissions for rheumatic complaints.

The impact of this form of arthritis related to either GI tract infection or STIs was felt by the military establishment. Troops and sailors were the frequent victims of epidemics of these infections and the British fleet in the Caribbean was virtually incapacitated by dysentery-related articular syndromes in 1804. In the Crimean war, 1200 (13%) of the 9500 soldiers invalided out of service were suffering from arthritis. Several historical figures are also believed to have suffered from this form of arthritis including Christopher Columbus the explorer, and Cellini the master goldsmith and sculptor. Columbus suffered incapacitating arthritis and ocular inflammation during his historical voyages to the New World.<sup>8</sup>

In 1916, Reiter described a symptom complex, akin to that recorded earlier by Brodie, in a German officer who had suffered dysentery in the trenches during the World War I. The use of the term Reiter syndrome to describe a clinical entity characterized by urethritis, arthritis, and ocular inflammation initially gained momentum until Reiter's unsavory role in the next great war as a camp physician involved with human experimentation came to light.<sup>9</sup> In the 1960s, the term reactive arthritis was proposed and this has now become the accepted terminology.<sup>10</sup>

The HIV epidemic has profoundly affected the practice of rheumatology in southern Africa and other parts of the world where HIV is highly prevalent. HIV-related arthritis is less frequently observed in Caucasian and Indian populations when compared to Africans.

## Direct Joint Involvement

### GONOCOCCAL INFECTION

Direct joint involvement takes the form of septic arthritis in the context of sexually transmitted infections. The causative organisms are either *Neisseria gonorrhea* or rarely, *Ureaplasma urealyticum*. This arthritis is not related to HLA B27. It can be polyarticular and a part of the classic arthritis, dermatitis syndrome associated with disseminated gonococcal infection (DGI). There is usually no chronic joint inflammation, spondyloarthritis, or the development of the classic forms of reactive arthritis.<sup>1,11</sup>

Patients usually present with fever, joint pain, dermatitis, and synovial sheath inflammation for a few days. Fever is usually high grade but may occasionally be absent. The joint pains may be migratory with resolution of pain, swelling, and redness from the initially involved joint when the next gets affected, or additive where several joints are involved in succession with no resolution of symptoms in the initially involved joints. Synovial sheath swelling of the dorsal aspect of the hands and wrist may be the initial manifestation, while the first joints to be involved may be the knees or ankles. Joint pain may resolve spontaneously in about 30% of patients but evolve into classic septic arthritis of one or

more joints in the remainder. Hand joints, wrists, knees, ankles and feet are commonly involved. In the usual forms of septic arthritis, only one large joint is involved and hand joint involvement is very uncommon. However, the septic arthritis of DGI characteristically involves more than one joint and the small joints of the hand are frequently affected. The sternoclavicular joint, temporomandibular joint and sacroiliac joints are seldom involved. In a minority of patients a symmetric polyarthritis may be noted.<sup>12</sup> Additional factors that contribute to the development of septic arthritis include concomitant HIV infection, malignancy, chemotherapy, diabetes, systemic lupus erythematosus, complement deficiencies, and intravenous substance use. The joints are swollen, red, and tender with synovial thickening and effusion along with limitation of movement. Joint radiology is usually non contributory due to the acute nature of the infection. Synovial fluid shows a brisk leukocytosis and culture is often positive. The blood culture is positive in a smaller percentage.<sup>11,13</sup>

When gonococcal septic arthropathy is suspected, samples should be sought from the cervix, urethra, pharynx, and rectum. In DGI, 50% of patients have a positive result for one of these mucosal sites. Gonococci are fastidious organisms to grow and require specific conditions. Nucleic acid testing from samples of synovial fluid can also help confirm the nature of the infection.

The skin lesions (Fig. 65.1) associated with this syndrome are described in detail in the chapter on DGI. In summary, they comprise tiny pustules or vesicles with a reddish base. These are neither itchy nor painful and are most often found on the extremities.

Patients may rarely show other features of DGI, namely, endocarditis, myocarditis, perihepatitis, pelvic inflammatory disease, and overwhelming sepsis with adrenal insufficiency and adult respiratory distress syndrome.<sup>11,13</sup>

Chronic arthritis due to gonococcal infection is extremely uncommon unless there has been inadequate treatment or the organism is resistant to the prescribed antibiotics. Serious joint destruction can be the consequence of such a problem. Occasionally, a gonococcal osteomyelitis may supervene due to direct extension from an infected joint.

There is a large differential diagnosis for the syndrome of fever, skin lesions, joint pains, and tenosynovitis. *Listeria*, *Staph. aureus*, coxsackie virus, echovirus, Epstein-Barr virus, cytomegalovirus, Hepatitis B, Hepatitis C, parvovirus B19, falciparum malaria, *Vibrio* infections and vasculitides can present in similar fashion. However, in the setting of STIs, it is important to differentiate the septic arthritis of DGI from a reactive arthritis. This condition tends to have a slower evolution over weeks rather than days and usually affects the lower limb in preference to the upper limb. Conjunctival inflammation and painless mucosal ulceration are important features, which are usually missing in patients with DGI. Further, the urethritis in reactive arthritis tends to be milder and less painful than that observed in gonorrhea.<sup>1,11,13</sup>

The management of patients with DGI and arthritis is with parenteral antibiotics based on antimicrobial sensitivity

testing. Response to adequate antibiotic therapy is usually prompt and the outcome excellent. Patients should be educated regarding the use of condoms and the treatment of sexual partners.

## Indirect Joint Involvement

### SYPHILIS

The re-emergence of syphilis as an important STI, especially in relation to HIV infection, is a major public health problem. This clinical setting provides ideal ground for atypical manifestations, an aggressive clinical course, an altered serologic response and sometimes a poor therapeutic response. Several long forgotten manifestations of syphilis need to be reviewed and osteoarticular complications are just one of them.<sup>1,14</sup>

Articular manifestations of syphilis were well-recognized in the preantibiotic era and comprise several clinical forms. Osteochondritis, osteitis, periostitis, and gumma of bone are well-recognized manifestations of congenital syphilis, while polyarthralgia, polyarthritis, spondylitis, tenosynovitis, and neuropathic arthropathy are features of secondary and tertiary syphilis.<sup>14</sup>

Osteochondritis affects the ends of long bones and manifests within the first six weeks of life. It responds well to treatment with penicillin. Osteitis and periostitis involve the shaft of long bones and show a similar response to therapy.

Between 5% and 10% of patients with secondary syphilis have joint pain.<sup>15</sup> An inflammatory arthritis, characterized by swelling and tenderness, is less frequent. When it occurs, it is symmetrical and mainly involves the large joints. It can thus be a differential diagnosis of rheumatoid arthritis. Although electron microscopy of synovial tissue from such patients has shown bodies that look like treponemes,<sup>16</sup> demonstration of the organisms by conventional methods has not been successful. Some patients with pain in the back mimicking spondylitis have also been described. These forms of articular disease respond well to treatment for syphilis.

In tertiary syphilis, joint involvement is usually due to neuropathy associated with tabes dorsalis.<sup>14</sup> Rarely, gumma of bone or joint may be found. The neuropathic joint is painless, is grossly swollen, and shows no features of inflammation. Radiologically, the bones show gross destruction and severe disorganization of the joint structure. There is invariably a large soft tissue swelling. The ends of the bones, surprisingly, do not show osteoporosis. A neuropathic joint requires support, splinting, and orthopedic fixation to optimize function.

### LYMPHOGRANULOMA VENEREUM

Lymphogranuloma venereum may be associated with the development of a rash, symmetrical polyarthritis, and a positive rheumatoid factor.<sup>1</sup> It could thus be a differential diagnosis of rheumatoid arthritis. This is an infrequently observed syndrome and its exact pathogenesis is unknown. Treatment of the underlying infection is usually followed by a good response.

### HEPATITIS B VIRUS INFECTION

Although arthritis in patients with jaundice was recorded over 150 years ago, its importance was recognized in 1970s. Arthralgia is a frequent component of the prodrome of hepatitis B affecting almost 50% of patients. About a third of these patients may actually develop a symmetrical arthritis of the hands, feet, knees, and ankles. An urticarial rash is observed in half the patients who develop the arthritis. The arthritis is usually self-limiting and tends to disappear with the appearance of jaundice.<sup>1</sup> Occasionally, patients with hepatitis B infection go on to develop polyarteritis nodosa. This form of systemic necrotizing vasculitis has protean clinical manifestations dominated by fever, weight loss, joint pain, mononeuritis multiplex, hypertension, testicular infarction, bowel ischemia, and renal infarction.<sup>17</sup> Patients may be deceptively normal looking with a potentially catastrophic illness lurking underneath. A high degree of suspicion is required. Some patients may demonstrate antineutrophil cytoplasmic antibodies (ANCA).<sup>17</sup> Immune suppression, plasmapheresis, and interferon therapy have all helped to reduce the previously high mortality.<sup>17</sup>

### Reactive Arthritis

Reactive arthritis is defined as sterile joint inflammation following distant infection.<sup>10,18</sup> It may be triggered by genitourinary infection, gastrointestinal infection, or an upper respiratory infection. It is a systemic disease of worldwide distribution with an equal sex ratio if acquired after a gastrointestinal or respiratory infection. The ratio of males to females in those who have sexually acquired reactive arthritis is close to 9:1. In general, reactive arthritis involves mainly young adults with a prevalence of 30–40/100,000 and an incidence of 5–28/100,000 per year reported in Finland. It has a strong association with HLA B27, which results in a near 50-fold increase in the probability of SARA. It follows a variable, usually self-limited course and predominantly affects the joints, skin, mucous membranes, eye, heart and blood vessels, and occasionally other organs or systems like the kidneys.<sup>1,18,19</sup> Approximately 15% of patients will, however, develop chronic joint problems.

Patients with reactive arthritides show involvement of the axial and peripheral joints as part of a spectrum where enthesitis is an important pathologic hallmark.<sup>20</sup> This is the area where tendons and ligaments attach to bones. Classification and diagnostic criteria have been established.<sup>21–23</sup> The study of these conditions in the clinic and the laboratory has afforded a unique opportunity to assess the range and impact of the interaction between the host and a group of microbes, away from the drama of an acute infection.<sup>24–30</sup>

Articular involvement ranges from mild arthralgia to severely disabling polyarthritis. It is usually asymmetrical and can be in the form of a monoarthritis, oligoarthritis (less than four joints) or polyarthritis. Weight bearing joints of the lower limbs are most frequently involved.<sup>1,10,18</sup> Isolated involvement of an upper limb joint is very uncommon unless the patient also has psoriasis. The distribution is knee (80%); ankle and metatarsophalangeal (60%); tarsal, wrist, proximal interphalangeal of lower limbs

(40%); elbow, metacarpophalangeal and proximal interphalangeal of upper limb (30%); shoulder, distal interphalangeal (20%); hip, acromioclavicular, sacroiliac (10%); and sternoclavicular (5%). The arthritis may be migratory but is most frequently additive.<sup>18</sup> Since the disease affects mainly young people, the initial manifestations of reactive arthritis are often considered to be some form of sporting injury.<sup>3,18</sup> The entire pattern of involvement generally evolves over one to several weeks. Once it has developed, it may either resolve spontaneously or persist requiring medication. The duration of a single nonresolving episode of reactive arthritis may vary from 3 to 12 months. In the presence of concomitant HIV infection, the course of reactive arthritis is more aggressive. The HIV epidemic has seriously impacted the practice of rheumatology in sub-Saharan Africa. In Zambia, over a 30-month period, 98% of 128 undifferentiated spondyloarthritis patients and 87% of 130 with reactive arthritis were found to be HIV positive. These patients had longer episodes of arthritis and took longer to attain remission.<sup>31</sup>

Inflammation of the finger and toe joints along with subcutaneous tissue results in the development of a sausage shaped digit, which is tender and inflamed.<sup>1,18</sup> This dactylitis affects about 15% of patients and is an important clinical feature of reactive arthritis. It is usually asymmetric. These patients also tend to have asymmetric involvement of several joints including the sacroiliac joints.<sup>18</sup> The hallmark of this form of inflammation is enthesitis. In all forms of reactive arthritis the entheses are inflamed and produce a typical clinical and radiological picture.<sup>20</sup> The most frequent form of enthesitis in clinical practice involves the heel and plantar fascia (Fig. 65.1). However, other important areas that could dominate the clinical picture include the ischial tuberosity, iliac crest, ribs, and the tibial tuberosity.

**Fig. 65.1:** Lesions of disseminated gonococcal infection on palms and feet. Courtesy: Radha Rani Mittal, Patiala, India.

**Fig. 65.2:** Lateral radiograph of the ankle showing a well-developed calcaneal spur in both the tendo achilles and the attachment of the plantar fascia.

Radiologically there are a wide spectrum of abnormalities observed.<sup>18</sup> Enthesitis can result in either an erosion or a spur formation. These erosions differ from the erosions of rheumatoid arthritis because they are extra synovial and often in relation with the shaft of the bone (Fig. 65.2). The erosions in rheumatoid arthritis are synovial in distribution and marginal in location on radiographs. The other feature distinct from rheumatoid arthritis is new bone formation. This takes the form of either whiskering or spur formation (Fig. 65.3). Spur formation around the calcaneum is very typical of all forms of reactive arthritis. Similarly, spur formation can be observed in radiographs of the knees and other involved joints. Enthesitis and inflammation of the sacroiliac joints can result in initial widening followed by sclerosis, new bone formation, and ankylosis<sup>18</sup> (Fig. 65.4). However, this involvement is usually asymmetric unlike that observed in patients with ankylosing spondylitis. Spinal enthesitis in reactive arthritis results in the formation of large asymmetric syndesmophytes unlike the fine symmetrical syndesmophytes observed in patients with ankylosing spondylitis<sup>18</sup> (Fig. 65.5).

Skin involvement takes the form of keratoderma blennorrhagicum (Fig. 65.6 & 65.7). It starts as a reddish macule that thickens and enlarges to form papules and plaques. It is associated with hyperkeratosis and may be histologically indistinguishable from psoriasis. Most frequently, it involves the soles of feet followed by the palm of the hands and is painless. It is more frequently observed in patients with sexually acquired reactive arthritis than in those with a preceding enteric or respiratory infection.<sup>1,18</sup>

Nearly a third of patients with sexually acquired reactive arthritis develop painless ulcers over the buccal mucosa, lips, tongue, palate, tonsillar pillars or throat. A similar percentage develop painless genital ulcers. In men, they take the form of circinate balanitis (Fig. 65.6), which is a painless geographic dermatitis of the glans penis in uncircumcised men. These lesions tend to resemble keratoderma blennorrhagicum in circumcised men.<sup>1,18</sup> In women, an erosive vulval inflammation is sometimes observed. Urethritis is a common manifestation and develops in up to 90% of patients

**Fig. 65.5:** Radiograph showing asymmetrical sacroiliitis in a patient with reactive arthritis.

**Fig. 65.6:** Characteristic heaped up scale of reactive arthritis syndrome (Reiter's) with onycholysis.

**Fig. 65.7:** Palmoplantar lesions of reactive arthritis. Note the dystrophic nails.

during the course of their illness even if they are sexually inactive. In the sexually active, the usual tendency is to ascribe all urethral symptoms to an STI. However, the failure to demonstrate an organism and the lack of response to conventional antibiotics should alert one to the possibility of a reactive inflammation.<sup>18</sup> The development of other features of the syndrome confirms it. Involvement of the prostate, prostatic urethra, uterine cervix, and fallopian tubes has been documented

About 15% of patients with reactive arthritis develop subungual hyperkeratosis resulting in the thickening and lifting up of the nail from their beds and imparting a yellowish brown discoloration.<sup>1</sup>

Ocular inflammation can develop in nearly half the patients with sexually acquired reactive arthritis. It can manifest as a mild conjunctivitis that may be easily missed. The most serious involvement is in the form of uveitis, which may be recurrent. It is usually confined to the anterior segment of the eye and manifests

as blurred vision and circumcorneal congestion. Keratic precipitates and cells in the anterior chamber are the usual findings. Repeated episodes of uveitis may result in the formation of a complicated cataract, development of glaucoma or posterior uveitis. All these complications may seriously impair vision and ocular inflammation requires urgent treatment. This may include topical steroid drops along with mydriatics for the milder episodes, and either local subtenon injection of steroids or oral steroids for more severe inflammation.<sup>32</sup> The other rarer forms of ocular involvement include episcleritis, keratitis, and corneal ulceration.

Visceral involvement in reactive arthritis affects the cardiovascular system and occasionally the kidneys. Cardiovascular involvement manifests as abnormalities of atrioventricular conduction (5–10%), complete heart block, acute aortitis resulting in aortic incompetence, myocarditis, pericarditis, and heart failure. All these manifestations are potentially life-threatening and require urgent management.<sup>33,34</sup> This may include pacemaker implantation and high-dose corticosteroid therapy. Renal involvement is in the form of an IgA nephropathy. There are several other very infrequent systemic manifestations that may occur in such patients including pleuro pericarditis, pneumonitis, meningoencephalitis, peripheral neuropathy, and thrombophlebitis.<sup>1</sup> It is a clinical challenge to ascribe these manifestations to reactive arthritis at the outset and all such patients require detailed investigation to exclude commoner causes before such a conclusion can be reached.

Investigations do not usually provide a conclusive diagnosis regarding the cause of reactive arthritis.<sup>18,34</sup> There may be a leukocytosis and other evidence of inflammation, but tests for Rheumatoid factor and ANA are negative. The synovial fluid also shows leukocytosis. Elegant microbiological studies involving PCR have demonstrated fragments of chlamydial DNA in the synovial fluid of some patients supporting an etiological role for this organism in the genesis of reactive arthritis.

The clinical course of reactive arthritis is very variable. As stated previously, each episode may last from 3 to 12 months and occasionally even longer.<sup>34</sup> There is roughly a 10–15% risk of recurrence annually.

Joint inflammation can be controlled with a judicious use of the nonsteroidal anti-inflammatory drugs (NSAIDs). For persons with a history of gastrointestinal ulceration, it is wiser to use a selective COX-2 inhibitor like Celecoxib (200–400 mg/day). However, the pain is occasionally so severe that patients require large doses of indomethacin (100–200 mg/day), naproxen (750–1500 mg/day), piroxicam (20–40 mg/day), or diclofenac (100–200 mg/day) for control of inflammation. Oral and injectable corticosteroids are very helpful in the control of severe initial inflammation and also to control flares. Attempts should be made to try and taper the dose to the minimum, which is effective as soon as control over symptoms is achieved.<sup>18,34</sup> For patients with a predominantly peripheral arthritis, sulfasalazine therapy provides good control. This drug is also useful in the management of some patients with spinal pain. Treatment is usually started with 1000 mg/day and built up to 2–3 g. Blood counts need to be monitored regularly, and glucose 6 phosphate

dehydrogenase deficient patients and those with a known allergy to sulfonamides should not be given sulfasalazine. Methotrexate therapy is also useful in the management of peripheral reactive arthritis. It is desirable to exclude hepatitis B and C virus infection and establish normal liver function before starting therapy at 7.5–15 mg/wk. The dose can be gradually built up to 20–25 mg/wk if necessary with monitoring of liver function, renal function and the hematology profile.<sup>34</sup>

The role of antibiotics in the management of patients with reactive arthritis is controversial. Some small studies have shown a benefit but several others have failed to demonstrate any advantage. Macrolides, ciprofloxacin, doxycycline, and minocycline have been used but there is no convincing evidence of their efficacy in either preventing the development of reactive arthritis or in curtailing the course of the arthritis when it develops.<sup>3,34</sup>

The use of infliximab and etanercept in the management of such patients has been recommended recently.<sup>34,35</sup> Usually these patients have become refractory to other modalities of treatment and have active disease. While there is usually an excellent short-term clinical response, the long-term outcome of this treatment is not known. There have been several instances of patients on this therapy developing clinically significant tuberculosis, autoimmune disease, and allergic reactions. With the availability of a completely humanized molecule, and with a better understanding of the implications of such therapy in patients with infectious diseases including concomitant HIV infection, the true place of biological therapy will emerge.<sup>34</sup>

## PATHOGENESIS

The role of infection in the development of arthritis has been speculative. In the case of rheumatoid arthritis, the lack of a temporal correlation has raised serious doubts regarding the validity of such a presumption. In the case of reactive arthritis, the close time-event relationship has made establishing this relationship a little easier. Elegant studies on patients, their genetic constitution, their serologic responses, synovial fluid characteristics and developments in the field of microbial identification and microbial gene expression have all resulted in the elucidation of a clearer road map to follow in the development of this condition.<sup>3,4,35,36</sup> Animal models have also contributed

**Fig. 65.8:** Dermal manifestations of reactive arthritis. Circinate balanitis.

significantly to the development of a clearer picture. The following section is based on the understanding reached in relation to chlamydial infection and its interaction with the host to produce articular inflammation as it is well-characterized and studied with good experimental models.<sup>3,4</sup>

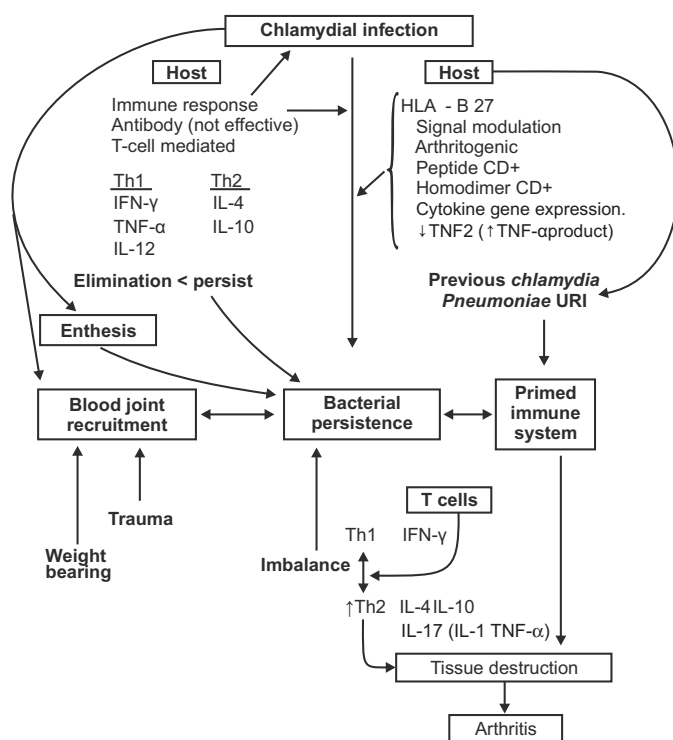

The key to the development of arthritis and enthesitis is the persistence of the organism in the host<sup>3,4,18,35,36</sup> (Fig. 65.9). Several factors contribute to this including the genetic constitution of the host, the genes expressed by the organism, quality of the immune response to the infection, previous exposure to the same or related organisms, the structure of the enthesis, blood joint recruitment, and the reaction that the persistence generates.

HLA B 27 is important, but not crucial, in the development of reactive arthritis.<sup>4</sup> Only 50–60% of patients with chlamydia-related reactive arthritis are positive but those with severe disease are more likely to be positive. Thus it probably contributes more to the severity of inflammation than the actual initiation. It has a role to play in the modulation of the initial signals that promote bacterial persistence rather than elimination.<sup>26</sup> It is also believed to play a part in the possible presentation of an arthritogenic peptide to CD8+

cells initiating a sequence of responses.<sup>4</sup> Although HLA B 27 itself traditionally works through the CD8+ cells being a MHC Class I molecule, its homodimer (with an unpaired cysteine moiety) may allow it to configure itself like a MHC Class II molecule and initiate a CD4+ response.<sup>4</sup> The reactive arthritis related to chlamydia, campylobacter, *Clostridium difficile*, salmonella, shigella, and yersinia is HLA B 27 dependant while that related to neisseria, ureaplasma, vibrio, staphylococci, streptococci, leptospira, brucella, mycobacteria, and hafnia is not.<sup>37</sup> Several other genes play a role in the development of ankylosing spondylitis and some of them may also play an important role in the development of reactive arthritis.

The host immune response to chlamydial infection results in the development of an antibody that may have a role in the prevention of future transmucosal infection. Further, previous exposure to an organism of the same species probably results in the priming of the immune system in a manner that promotes persistence over elimination. Specifically, the host T cell response is more Th2 (IL 4 and IL 10 driven)<sup>3,25</sup> unlike the Th1 response that is driven by interferon-gamma, tumor necrosis factor-alpha and IL 12, which favors the elimination of bacteria. The priming of the immune system to react in this way is attributed to previous exposure to respiratory chlamydial infection. Frequent exposure promotes the development of the Th2 response that allows the Chlamydia to survive in cells. Additionally, *C. trachomatis* heat shock protein 60 (CT-Hsp60) cross reacts with that of *C. pneumoniae*.<sup>3</sup> Persistent *C. trachomatis* infection may allow the release of CT-Hsp60 from infected cells and the subsequent development of anti-CT-Hsp60. Stressed cells infected with *C. trachomatis* may allow the surface expression (sf-Hsp60) of the normally, intracellular, sequestered Hsp60. These antibodies can result in an autoimmune attack, which may be the basis of arthritis, vasculitis, atherosclerosis, and other diseases. Further, immune complexes comprising anti-CT-Hsp60 and circulating Hsp, both chlamydial and human can deposit in the kidney.<sup>38</sup>

The anatomy of the enthesis also favors persistence.<sup>20</sup> The rich blood supply facilitates the lodging of the organisms in close vicinity to the joints. Microtrauma and weight bearing probably magnifies this effect and this may explain why the weight bearing lower limb joints are more often affected.<sup>3</sup> These factors contribute to the recruitment of organisms into the joint, while the Th1/Th2 imbalance allows persistence and tissue destruction. Synovial fluid levels of interferon-gamma and tumor necrosis factor-alpha, which favor bacterial elimination are relatively low in patients with reactive arthritis compared to rheumatoid arthritis while those of Th2 cytokines, IL 4, IL 10, and IL 17 are high.<sup>3</sup> Evidence of chlamydial persistence in the synovial membrane is available in the form of demonstration of the elementary bodies by immunofluorescence and reticulate bodies by electron microscopy.<sup>39</sup> The transcriptional activity of the organism, suggesting active replication, has been shown by demonstration of mRNA and DNA.

**Fig. 65.9:** Diagrammatic representation of the pathogenesis of reactive arthritis related to chlamydial infection. Important host factors include the genetic constitution, the immune response to the infection and previous exposure to similar organisms. The interaction between the immune response and genetic factors favors bacterial persistence and the development of enthesitis. The imbalance between the Th1 and Th2 responses in the presence of a primed immune system facilitates tissue inflammation, destruction and the development of arthritis.

There is scientific evidence to support the claim that patients suffering from Chlamydia-related reactive arthritis mount immune reactions that favor the intracellular persistence of the organism over its elimination. This phenomenon permits the recruitment of infected material to the enthesis and promotes the development of an immunologically maintained inflammatory cascade that results in damage.

## Introduction

In this chapter is discussed the biology of human immunodeficiency virus (HIV) the causative agent of Acquired Immunodeficiency Syndrome (AIDS), the natural history of HIV infection, its classification, various stages in course of the disease.

It is well-established now that untreated HIV disease progresses relentlessly in almost all infected persons, from a clinically silent infection to severely damaged immunologic function resulting in the AIDS.<sup>1</sup> Following infection, the time before the onset of clinical disease varies from months to years. The duration is influenced by many different factors which may be primarily host related like the age and genetic makeup of the individual, but not by gender or mode of acquisition of the virus.

The disease, if left untreated, leads to death over a median period of about 10 years. However, the time it takes to cover this spectrum varies greatly ranging from one year or less in some patients, to a still unknown upper limit in others. This upper limit has reached nearly 20 years in a few individuals called “long-term non-progressors.” Eventually, it causes death in most people. Various clinical syndromes may occur during the course of HIV disease. Interaction between the host, HIV and environmental factors may determine the course of the disease, clinical manifestations and the rate of disease progression in each individual.

This chapter primarily addresses infection with HIV-1, although HIV-2 is occasionally discussed.

## The Virus

The Retroviridae are a large family of viruses that are associated with many diseases including malignancies, wasting diseases, neurological disorders and immunodeficiencies. Despite the variation in their interaction with the host, all retroviruses are similar in virion structure, genome organization, and mode of replication. A retrovirus is classified as a virus that attaches itself to the host cell and transcribes its viral RNA genome into cellular DNA. The result is the host cell and the virus become one, making it difficult for the normal immune response to combat it. Further,

instead of killing the cell almost immediately after injecting its genetic material, as is the case with many DNA viruses, the retrovirus is able to live as part of the host for an extended period of time. Thus the persons infected with a retrovirus might live for some time without experiencing any strong symptoms and then suddenly find themselves completely overwhelmed. This is the case with the HIV. Only after a long period of incubation do the symptoms of AIDS manifest themselves. The history of retroviruses began in 1908 with the discovery of a filterable transmissible agent associated with disease in chickens.<sup>1</sup> In the next few decades, significant research was carried out on murine leukemia viruses. In 1970, the reverse transcriptase enzyme present in retroviruses was discovered by two different scientists independently (David Baltimore and Howard Temin).<sup>2,3</sup> In 1980, Robert Gallo and his colleagues reported the isolation of the first human retrovirus, which they named Human T-lymphotropic virus or HTLV-1 due to its tropism for T lymphocytes.<sup>4</sup> So far, two evolutionary distinct groups of human retroviruses have been found: (i) the leukemia virus (HTLV-I and HTLV-II), and (ii) the HIVs (HIV-1 and HIV-2). The HIV-1 and HIV-2 viruses were isolated in 1983 and 1986, respectively.<sup>5-7</sup> Retroviruses have been traditionally divided into three subfamilies based on their pathogenicity, that is, *Oncovirinae*, *Lentivirinae*, and *Spumavirinae*. Their classification is given in the Table 66.1.<sup>8</sup>

## Origin of HIV

Korber et al.<sup>9</sup> used phylogenetic analysis in combination with known sampling dates to estimate the year of origin of the HIV-1 group of viruses, which are the cause of the main AIDS pandemic. By the time HIV-1 and HIV-2 were detected in the 1980s, several separate and independent HIV lineages were found to be already causing infections in human populations in Africa.<sup>10</sup> HIV appears to have been transmitted to human beings from at least two different non-human primates infected with simian immunodeficiency viruses (SIVs). The HIV isolates that were transmitted from chimpanzees are known as HIV-1 and those transmitted from sooty mangabey monkeys are known as

**Table 66.1:** Classification of Retroviruses

Subfamily	Group	Examples
Oncovirinae	Avian leukosis sarcoma	Rous sarcoma virus (RSV) Avian myeloblastosis virus (AMV) Avian erythroblastosis virus (AEV) Rous associated virus (RAV)-1–50 RAV-O
	Mammalian C type	Moloney murine leukaemia virus (Mo-MLV) Harvey murine sarcoma virus (Ha-MSV) Abelson murine leukaemia virus (A-MLV) AKR-MuLV Feline leukaemia virus (FeLV) Simian sarcoma virus Reticuloendotheliosis virus (REV) Spleen necrosis virus (SNV)
	B type viruses	Mouse mammary tumor virus (MMTV)
	D type viruses	Mason-Pfizer monkey virus (MPMV) “SAIDS” viruses
	HTLV-BLV group	Human T cell leukaemia (or lymphotropic) virus (HTLV) Bovine leukaemia virus (BLV)
Lentivirinae	Lentiviruses	HIV 1 and 2 Simian immunodeficiency virus (SIV) Feline immunodeficiency virus (FIV) Visna-maedi virus Equine infectious anemia virus (EIAV) Caprine arthritis-encephalitis virus (CAEV)
Spumavirinae	“Foamy” viruses	Simian foamy viruses (SFV)

HIV-2. HIV-1 is most closely related to SIVcpz isolated from the chimpanzee subspecies *Pan troglodytes troglodytes*.<sup>11–13</sup> The most diverse forms of HIV-1 are found in the geographic region corresponding to the region where *Pan troglodytes troglodytes* is found in west equatorial Africa.<sup>14,15</sup> HIV-1 and SIVcpz sequences are closely related phylogenetically, suggesting that there are shared viral lineages in humans and chimpanzees. Similarly, HIV-2 is most closely related to SIVsm natural infection in sooty mangabey monkeys. The natural range of sooty mangabey monkeys overlaps the geographic region where the most diverse HIV-2 viruses have been identified. HIV-2 and SIVsm sequences are closely related in phylogenetic tree analysis.<sup>11–13</sup> It is interesting that HIV-2 does not kill sooty mangabeys, and has a less virulent course in humans, which suggests it evolved much earlier than HIV-1. Analysis of sequence data over the last few years indicates that the last common ancestor of the HIV-1 probably originated around 1930.<sup>9</sup>

There was a marked industrial and economic growth in central African cities such as Kinshasa and Brazzaville in the early part of the 20th century. During this century, easy availability of guns made it easier for man to hunt chimpanzees for their meat.

Increased reliance on chimpanzee meat and changes in hunting/ butchery practices resulted in increased risk of humans coming in contact with chimpanzees. This probably resulted in HIV adapting to humans and causing infection in those who came in contact with chimpanzees and their biological products.<sup>16,17</sup> Subsequently, during the later part of the 20th century, widespread use of air travel made it easier for the spread of HIV to the different regions of the world.

## Virus Structure

HIV comprises a nucleoprotein core surrounded by other protein coats (Fig. 66.1). Under the electron microscope, it appears as a central electron dense core region surrounded by an envelope. On its outer surface is a lipid bilayer containing surface (gp120) and transmembrane (gp41) envelope glycoproteins. The gp120 contains viral determinants that bind to the receptor present on the host cell surface. gp41 contains the transmembrane and cytoplasmic domains that anchor the gp120 onto the surface of the viral lipid layer.

The nucleoprotein core of the virion comprises of two copies of the viral genomic RNA (positive strands, which are identical) and associated RNA molecules, together with *gag* and *pol* protein products, i.e., the nucleocapsid (NC) protein, the capsid (CA) protein and viral enzymes integrase, protease (PR) and reverse transcriptase (RT). The matrix (MA) *gag* protein lines the inner surface of the lipid bilayer.

The capsid (CA) *gag* protein forms the icosahedral viral core. It is hydrophobic and is the major internal structural feature of the virion, that is, the shell of the viral core. Mutations in the CA protein may result in elimination of virus assembly during the late stage of viral replication.

The nucleocapsid (NC or p9) *gag* protein is a small basic protein found in association with viral genomic RNA. It is usually phosphorylated on serine residues, which may be an important determinant for viral assembly. A pair of zinc-finger motifs in the NC protein mediates binding to a region near the 5' end of the viral RNA, which is known as the packaging signal.

## ENZYMES IN HIV VIRION

The *pol* gene codes for the viral enzymes reverse transcriptase, integrase, and protease.

## Reverse Transcriptase

The primary *pol* product is cleaved by the virion protease to yield the amino-terminal RT peptide and the carboxy-terminal IN (or integrase) protein. The RT peptide has activities necessary for DNA synthesis, which include RNA and DNA directed DNA polymerase, ribonuclease H, and some other nucleolytic activities. The viral polymerase (reverse transcriptase enzyme or RT) is an error-prone enzyme and lacks proof-reading capacity, which results in an error frequency that has been estimated to  $3.4 \times 10^{-5}$  during the reverse transcription.<sup>18</sup> This corresponds to

**Fig. 66.1:** Diagrammatic representation of human immunodeficiency virus structure. *Source:* [www.niaid.nih.gov/factsheets/howhiv.htm](http://www.niaid.nih.gov/factsheets/howhiv.htm).

approximately one new nucleotide substitution per genome per replication cycle.<sup>19</sup> The reverse transcription results in formation of a variety of HIV-1 quasispecies that can have altered cell tropism and drug resistance patterns that can escape the neutralization by the host immune system.

### Integrase

After the viral genomic RNA is reverse transcribed into viral DNA by the reverse transcriptase enzyme it is transported to the host cell chromosomal DNA to form the provirus. This step requires the activity of the viral IN (integrase) protein. The site of integration of the retroviral DNA into the host chromosomal DNA is usually random, although some target sites may be preferred.

### Protease

HIV-1 protease (HIV PR) is essential for the life cycle of HIV. HIV PR cleaves newly synthesized polypeptides at the appropriate places to create the mature protein components of an infectious HIV virion. Without effective HIV PR, HIV virions remain noninfectious. Thus, mutation of HIV PR's active site or inhibition of its activity disrupts ability of the HIV to replicate and infect additional cells, making HIV PR inhibition the subject of much successful pharmaceutical research. In fact the protease inhibitors were "designed" from a detailed knowledge of the structure of HIV PR.

### Envelope Proteins

The *env* gene encodes for a 160 KD precursor glycoprotein composed of 850 amino acids, which is cleaved by an endopeptidase into two glycoproteins, viz gp120, and gp41. There are four highly conserved regions/domains (C1–C4) interspersed with regions of high variability (V1–V5) in the gp120 protein. It is the high degree of variability in the envelope gene, which makes it problematic to prepare a vaccine that will protect against all strains of HIV-1.

### HIV Receptors and Coreceptors

Although HIV is one of the most recently discovered retrovirus, CD4 was the first retrovirus receptor to be identified (Fig. 66.2). The cluster of differentiation (cluster of designation) (often abbreviated as CD) is a protocol used for the identification and investigation of cell surface molecules present on white blood cells. CD molecules can act in numerous ways, often acting as receptors or ligands (the molecule that activates a receptor) important to the cell. A signal cascade is usually initiated, altering the behavior of the cell. Some CD proteins do not play a role in cell signaling, but have other functions, such as cell adhesion.)

In HIV-1 infected adults, the CCR5-Δ32 and CCR2-64I alleles have been associated with a delay of 2 to 4 years in progression to AIDS. In HIV-1 infected children, the presence of the CCR2-64I allele is associated with a delay in the development of AIDS and death. The SDF-1 mutant allele tends

**Fig. 66.2:** Binding of gp120 and gp41 of HIV-1 with CD4 and chemokine receptor on surface of cell. However, expression of CD4 receptor on the cell surface is not enough to allow HIV entry into the cells; for example, HIV-1 cannot infect mouse cells that have been engineered to express CD4.<sup>20</sup> HIV-1 uses several coreceptors for cell entry besides the CD4 receptor. Chemokine receptors (CCR-5 and CXCR-4) and have been shown to be important coreceptors for HIV infection of macrophages and T-lymphocytes, respectively.<sup>21</sup> Allelic variants for the CCR 5, CCR 2, and stromal derived factor, SDF-1, ligand for the CXCR-4, have been recently identified.

to accelerate disease progression and death. Among SDF-1 3'A carriers, heterozygotes developed AIDS in almost half the time than SDF-1 'Wild' type homozygotes. Moreover, children with

an SDF-1 3'A allele tend to progress to death more rapidly than the wild-type group.

## Structure and Expression of the HIV-1 Genome

The proviral DNA form of the HIV-1 genome consists of 8.5–9 kb of protein coding information, flanked on either side by a pair of identical long terminal repeats (LTRs) (Fig. 66.3). The coding portion encodes for at least 9 recognized genes. These are the virion structural genes (*gag*, *pol*, and *env*), the regulatory genes (*tat*, *rev*, and *nef*), and the accessory genes (*vpu*, *vpr*, and *vif*). The genomic structure of HIV-2 is similar to that of HIV-1 but instead of *vpu*, there is the *vpx* gene in HIV-2.

Transcription of the provirus is controlled by a single promotor in the 5' LTR region and gives rise to a 9 kb primary transcript containing all nine genes. This primary transcript can be either packaged as such into virion particles to form the viral RNA genome or can be spliced into various mRNAs specifying the individual gene products. The primary HIV-1 transcript contains at least four donor (5') and six acceptor (3') potential splice sites.<sup>22</sup> HIV-1 mRNAs fall into three size classes, each with specific functions. The unspliced 9 kb primary transcript that can be packaged into virions or serve as mRNA for *gag* and *pol* or a heterogeneous class of partially spliced mRNA, which code for *env*, *vif*, *vpu*, and *vpr* proteins and for a single exon form of *tat*. Each of these mRNAs is 4–5 kb long. Additionally, another heterogeneous class of viral mRNA, each about 2 kb long and spliced at all potential splice sites is expressed. These codes for viral proteins *rev*, *nef*, and the two exon forms of *tat* (Table 66.2).

**Fig. 66.3:** Diagrammatic representation of the structure of HIV-1.

**Table 66.2:** Important Features of the HIV Genome

Gene/Protein	Regulation	Function
<i>env</i>	Structural	Codes for outer protein coat gp160 (then a protease enzyme splits it into gp120 and gp41)
<i>gag</i>	Structural	Encodes internal proteins (p17, p24, p7, and p9: the nucleocapsid core)
<i>pol</i>	Structural	Encodes the HIV core: p7, p9, RNA genome, reverse transcriptase, ribonuclease, integrase, protease
<i>tat</i>	Positive regulatory	Trans-activator of transcription. Could hasten viral protein production of proviral genome several thousand times. Up-regulates <i>rev</i> , <i>nef</i> , and itself
<i>nef</i>	Negative and positive	“Negative Regulation Factor”. Reduces the rate of RNA initiation (prevents proviral DNA from making more HIV proteins). Also negatively regulates <i>tat</i> and <i>rev</i> . Increase in <i>nef</i> suppresses viral replication. Many HIV strains have defective <i>nef</i> and may sustain latency period
<i>rev</i>	Positive/negative	“Regulator of Expression.” Acts as a genetic switch Prevents RNA expression, the more <i>rev</i> , the more full-length RNA is present and thus the greater amount of expression of <i>env</i> proteins. Downregulates <i>tat</i> and itself
<i>vpr</i>	Weak positive	Transcriptional activator. Moderately stimulates LTR
<i>vpu</i>	Negative?	Not found in HIV-2. If <i>vpu</i> is defective, viruses replicate more quickly Suppresses CD4/ <i>env</i> interactions in the cell
<i>vif</i>	Infectivity	Encodes “virion Infectivity Factor.” Increases the infectivity of HIV. Increases efficiency of cell-to-cell (possibly human-to-human?) transmission

During the early phase of HIV infection, only the fully spliced regulatory mRNAs can be detected in the cytoplasm of the infected cell.<sup>23</sup> Cytoplasmic expression and subsequent translation of the structural mRNAs leading to the production of virions occurs only late in the viral life cycle in response to the viral regulatory protein *rev*.<sup>24</sup> The regulatory proteins *tat*, *rev*, and *nef* proteins together act to either up regulate or down regulate the rate of HIV viral replication in the infected host cell.

The *nef* gene has been detected in all known retroviral genomes. A well-established function of *nef* is the down regulation of CD4, which is the primary receptor for HIV.<sup>25,26</sup> *nef* acts by inducing CD4 endocytosis resulting in its degradation in lysosomes.<sup>27</sup> Some studies have revealed that deletion in the *nef* gene could alter the progress of disease in a HIV infected individual.<sup>28</sup> The *nef* genes of HIV and SIV are dispensable *in vitro* but are essential for viral spread and disease progression *in vivo*. *nef* has been found to be necessary for the maintenance of high viral loads and for the development of AIDS in macaques.<sup>29</sup> A *nef* containing HIV-1 molecular clone induced severe depletion of human thymocytes in immunodeficient (SCID) mice containing human lymphoid tissues (SCID—hu) within 6 weeks of infection but a *nef* deleted HIV-1 did not.<sup>30</sup>

## Replication Cycle of HIV

Briefly, the HIV replication cycle can be divided into two phases. The first phase involves the interaction between viral envelope proteins and specific host cell receptors (CD4 and CCR5/CXCR4) followed by fusion of viral and cell membranes, and the entry of the virion core into the target cell cytoplasm. Synthesis of double-stranded DNA by reverse transcription using the single-stranded RNA genome as template is followed by transport of the DNA associated with the virion proteins to the nucleus of the cell and the

integration of the viral DNA into the host chromosomal DNA using the integrase enzyme to form the provirus.

The second phase involves the synthesis of viral RNA by RNA polymerase II using the integrated provirus as the template, followed by processing of the transcripts of the HIV genomic RNA as well as mRNAs for the production of the spliced and unspliced viral mRNA transcripts that encode the regulatory and structural viral proteins. Subsequently, assembly of the precursor structural proteins along with genomic length RNA and budding of the virion particles from the host cell surface takes place along with maturation of the precursor polyproteins to form the infectious viral particle (Fig. 66.4).

## Cell-Surface Binding of HIV

The HIV infection starts with the attachment of HIV by way of the gp120 protein to the CD4 target cell. Virus entry into

**Fig. 66.4:** Emergence of virions from the host cell (electron micrograph).

cells results from the fusion of viral and cell membranes, a process that depends on binding of virus *env* proteins to specific host-cell surface receptors. The CD4 receptor for HIV is composed of four extracellular immunoglobulin (Ig)-like domains and is expressed at the surface of a subset of T lymphocytes and some macrophages.<sup>31</sup> The virus can also infect several cell types of glial and neuroblastoma cell lines<sup>32,33</sup> (Table 66.3) in a manner that is consistent with direct fusion between viral and cell surface membranes.<sup>34</sup> This process is believed to be driven initially by conformational changes in *env* following CD4 binding that expose fusion peptide virus domains located at the amino terminus of gp41.<sup>35</sup> Other possible modes of binding to cells include the binding of antibody-coated viruses to Fc receptors on the surface of macrophages, a process that might explain antibody-mediated enhancement of virus infection, and the high-affinity binding between virus and host cells. The post-binding events required for HIV-1 and cell membrane fusion are less well-understood.

## Reverse Transcription

The reverse transcription pathway generates a linear DNA copy of the viral RNA genome. This step occurs inside a viral nucleoprotein complex and requires the coordinated activities of reverse transcriptase (RT), an RNA and DNA dependent DNA polymerase.<sup>36</sup> The single most important feature of HIV-1 that makes it a difficult target for therapeutic intervention is the high

degree of nucleotide sequence variation between different viral strains.<sup>37</sup> This variability partly reflects the poor fidelity of RT, because it lacks a 3'-5'-exonuclease proofreading activity. Up to 10 incorrect bases may be incorporated during each round of HIV-1 replication.<sup>38</sup> The mutations incorporated by retroviral RTs include amino acid substitutions, 1/+1 frameshifts, and deletions of nucleotide sequence.<sup>39</sup> Reverse transcription generates diverse viruses that can have altered cell-type tropisms, viral "fitness," escape from protective immunity, most commonly, drug-resistance, even before treatment.

## Integration of Viral DNA into Cellular Genomic DNA

The nuclear viral complexes serve as the machines that integrate viral DNA into host cell chromosomal DNA to form a provirus. This step is critically dependent on the activity of the viral integrase enzyme.<sup>40</sup> Retroviral DNA can be integrated into the host genome at a large number of essentially random sites.<sup>41</sup> Integrated retroviral DNA is called "provirus." HIV provirus can survive for years without expression in lymphocytes in a "resting"/"latent"/"dormant" state, where it appears to be safe from immune attack or antiviral drugs.

## Viral Protein Expression

The expression of viral genes needs the collaborative activities of the host cell transcription machinery (RNA polymerase and

**Table 66.3:** Cell Types Affected by HIV

Name	Structure/Function	Impairment in AIDS
<b>CD4+ T-cells</b>	Helper cells that recognize antigen presented by APCs (antigen presenting cells) in context of major histocompatibility complex (MHC) Class II	Functional (IL-2 production) and proliferative decline over time
<b>CD8+ T-cells</b>	Cytotoxic T-cells that recognize antigen presented by APCs in context of MHC Class I. Kill infected cells	Subsets influenced variously; counts increase over time. IL-12 levels are up at first in HIV, but subsequently decline
<b>Memory T-cells</b>	T-cells with quickened response to second exposure of same antigen; these cells express CD 45 receptor (CD45 RO are so-called "naive" cells)	CD 45 RA/RO drop
<b>B-cells</b>	Identify extracellular antigens and secrete antibody in plasma	Hypergammaglobulinaemia
<b>Monocytes/-</b>	cells	HIV infects these cells directly; does not appear to inhibit cytokine production, however
<b>Macrophages</b>	Antigen presenting cell (APC)	
<b>Langerhans/dendritic cells</b>	Antigen presenting cell (APC). Langerhans cells in skin can migrate into lymph system becoming dendritic cells	Impaired function
<b>Follicular dendritic cells</b>	Role as APC in capturing infectious agents on skin and mucous membranes in tree-like branches extending out from cell body	HIV can use these cells to gain access to the body through undamaged mucous membranes, other roles in pathogenesis still unclear
<b>Natural killer (NK) cells</b>	Assist in killing cells marked or coated by antibodies	Impaired function in HIV
<b>Kupffer cells</b>	Macrophages within liver	Infected by HIV
<b>Epithelial cells</b>	Skin primary structural component; lining of blood vessel walls and gut	Some types of epithelial cells can be infected by HIV, also, around brain, gut, and cervical area. Destruction of epithelial cells separating blood-brain barrier
<b>Sperm</b>	Male germ cell; motile cells	HIV can infect these cells; HIV appears to "ride" within sperm "head"
<b>Ova</b>	Female egg cell	Protected by amniotic sack

transcription factors) and viral regulatory proteins (*tat* and *rev*). The spliced viral mRNA transcripts give rise to *env* and to the regulatory *tat*, *rev*, and *nef* proteins. Unspliced transcripts encode the Pr55 *gag* and Pr160 *gag-pol* fusion proteins and also serve as genomic RNA packaged into newly assembling virus particles.<sup>42</sup>

## Virus Assembly

Newly synthesized HIV core proteins, enzymes and RNA gather just within the cell membrane and at the same time the envelope proteins aggregate within the membrane. An immature viral particle forms and pinches off from the cell and acquires an envelope that includes both the cellular and HIV proteins from the cell membrane.

## Envelope Proteins

Retroviral *env* proteins are synthesized within the endoplasmic reticulum (ER) of infected cells and are transported to the cell surface by the host-cell secretory pathway. Within the ER, monomers of gp160, the precursor HIV *env* protein, associate with molecular chaperone (BiP), before folding and oligomerization.<sup>43</sup> Once *env* is expressed in the infected cell, synthesis of cell-surface CD4 is down regulated, so that the cell becomes resistant to superinfection. During or soon after budding, retroviral particles mature when the *gag* and *gag-pol* polyproteins get cleaved into mature protein products by viral protease. This cleavage is an essential step in the maturation of retrovirus particles, because mutations in protease lead to production of non-infectious virus particles that contain uncleaved core proteins.<sup>44</sup> The mature virions that are released from the cell are competent to restart the replication cycle in other target cells.

## Early Events in HIV Infection

HIV is transmitted primarily through sexual contact, and hence genital mucosal surfaces are the portal of entry for HIV virus. Mucosal surfaces, including the oropharynx, rectum, and genital mucosa, are the sites rich in Langerhans cells—dendritic cells that trap antigens and virus particles. Dendritic cells trap the antigen through the receptor DC-SIGN which is instrumental in transporting the virus to the draining lymphoid tissue where the virus infects CD4 lymphocytes. The DCs and CD4 cells of mucosal surface may also get infected and actively produce the virus. Within hours of exposure of genital mucosa to the virus, multiplying virus may be detected in the draining lymph nodes. When female macaques were experimentally inoculated with SIV through the intravaginal route, the virus was first found in association with mucosal Langerhans cells.<sup>45</sup> Infection of dendritic cells and T cells in the genital mucosa can be detected within 18 hours after inoculation.<sup>46</sup> Contact between SIV and the vaginal mucosa for as little as 2 hours is sufficient to result in infection. Within a few days, the virus can be detected in neighboring lymphocytes and monocytes and then in the regional lymphoid tissues. Subsequently, primary viremia leads

to widespread dissemination of the virus, seeding of lymphoid tissues throughout the body resulting in acute HIV infection.

## Virus Multiplication and Establishment of Pool of Latently Infected CD4 Cells

During the time of primary viremia of HIV infection, a large numbers of infected cells in the peripheral blood and high titers of infectious virus in the plasma can be detected. These include titers as high as  $10^7$  HIV particles/ml.<sup>47</sup> These titers decline rapidly as effective virus-specific immunity develops in the host. Virus often becomes undetectable in the plasma, and the number of infected cells in the circulation may decline to less than 1 in 1 million peripheral blood mononuclear cells.

Virus titers in the blood begin to decline even before neutralizing antibodies can be detected suggesting that some other immunologic mechanism must be responsible for the initial control of virus replication. There is evidence that antibody dependent cellular cytotoxicity and HIV-specific cytotoxic T lymphocytes appear before the neutralizing antibodies become detectable.<sup>48,49</sup> The role of innate immune responses in initial control of virus multiplication is also being very actively explored. At one stage even though the virus appears to have disappeared from the blood, HIV replication continues unabated in lymphoid tissues. Studies of lymph node biopsies, using nucleic acid hybridization techniques that detect HIV RNA and DNA sequences in lymphoid tissues in patients in the early stages of HIV infection, have demonstrated active virus replication in the lymph nodes even during the clinically latent stage of infection.<sup>50</sup> These observations prove that HIV is never truly latent but instead causes a chronic active infection with continuous virus production at all stages of disease. Recent reports indicate that Gut Associated Lymphoid Tissue is a major site where the virus multiplies leading to the destruction of CD4 cells; paradoxically this co-exists with immune activation that sustains HIV infection. HIV preferentially infects memory CD4+ lymphocytes. Activated CD4+ cells are more easily infected by HIV-1 since they express higher levels of chemokine receptors that serve as coreceptors for the virus. Further, activated cells express high levels of nuclear transcription factors, which are required for expression of HIV-1 genes from proviral DNA. Thus, most of the infected activated CD4+ cells are productively infected and die within a few days. Resting CD4+ cells are occasionally infected, and some infected activated cells may revert to a resting state. These cells constitute the reservoir of latently infected resting CD4+ cells. It is during this period that the latent reservoir is established. This HIV reservoir in the resting CD4+ cells is refractory to antiretroviral treatment and immune mechanisms.

Within the lymph nodes and related organs, large amount of virus gets trapped within networks of specialized cells called follicular dendritic cells (FDCs). These are located in the germinal centers of the lymph nodes. They trap invading pathogens (including HIV) and hold them until B cells become available to initiate an immune response. B cells are followed by CD4+

T cells, which reach the germinal centers to assist B cells. CD4+ T cells, the primary targets of HIV, probably become infected in large numbers as they encounter HIV trapped on FDCs. HIV trapped on FDCs remains infectious, even when coated with antibodies. Once infected, it is possible for the CD4+ T cells to leave the germinal centre and infect other CD4+ cells that collect in the lymph node surrounding the germinal centre. Over years, even when little virus is readily detectable in the blood, significant amounts of virus accumulate in the germinal centers, both within infected cells and bound to FDCs. In and around the germinal centers, numerous CD4+ T cells get activated by the increased production of cytokines such as tumor necrosis factor (TNF)- $\alpha$  and interleukin (IL)-6, possibly secreted by B cells. Activation allows uninfected cells to be more easily infected and increases replication of HIV in already infected cells.

## Factors Influencing HIV Disease Progression

### HOST FACTORS

In adults, HIV infection progresses more rapidly in older people. Studies of adult hemophiliacs suggest that their progress to late symptomatic disease is faster than that of hemophiliac children. Transfusion recipients over 60 years of age had more rapid disease progression than their younger counterparts.<sup>51</sup> However, age was not an independent predictor of disease progression in a study on intravenous drug users,<sup>52</sup> and its significance in disease progression in homosexual men is unsettled.

Gender does not appear to have a major influence on disease progression, although natural history studies of HIV disease in women are lacking and the independent role of gender has not been extensively studied. Ethnicity or race also does not appear to influence disease progression; however, host genotype may be influential.<sup>53</sup> In the US, the incidence of AIDS in lower income groups has been rising since 1987,<sup>54</sup> and is likely to reflect the high prevalence of high-risk behaviors, inequitable access to medical care, and poor utilization of medical resources in these groups.

Approximately 5% of HIV infected patients will remain clinically well without immune deterioration for a decade or more after seroconversion and are known as “long-term survivors” or long-term nonprogressors. A recent study of long-term survivors showed that they have a strong CD8+ lymphocyte response and a broad and strong neutralizing antibody response to HIV-1. There is also evidence that there may be some attenuation of the HIV isolates in this patient group.<sup>55</sup>

### HIV RISK GROUPS

It is possible that HIV seropositive intravenous drug users, who have an increased incidence of pulmonary tuberculosis and serious bacterial infections, are more likely to progress rapidly to AIDS. Poverty and poor access to medical care may largely explain this variation.<sup>56</sup>

### VIRAL AND OTHER COFACTORS

In a study of HIV infected hemophiliacs, those who were cytomegalovirus (CMV) seropositive had a 2–4-fold higher risk of progression to late symptomatic disease than those who were seronegative.<sup>57</sup> This finding suggested that CMV may be a cofactor and the rate of disease progression in seropositive hemophiliacs was equivalent to those of HIV infected homosexuals who are almost universally seropositive for CMV. There is no clinical evidence that Epstein–Barr virus (EBV), human herpes virus 6 (HHV6), and hepatitis B virus act as cofactors in HIV disease. However, along with herpes simplex virus, these agents have all been shown to enhance HIV replication *in vitro*. It has been postulated that *Mycoplasma fermentans* may be a cofactor in HIV infection, but a recent study did not show any evidence for this.<sup>58</sup> Coinfection with both HIV 1 and HIV 2 has been reported but the rate of disease progression with dual infection is unknown. Hepatitis C virus is known to cause rapid progression of HIV disease.

### DEFECTIVE CORECEPTORS

HIV must bind to the surface protein called CD4 receptor in order to infect a cell. Another cell surface protein called “chemokine receptor” is also necessary for efficient HIV entry into the cell. CCR5 is one such coreceptor for which many individuals in the population carry a mutant gene (Delta-32 deletion). This mutation prevents the gene from producing a product that HIV can use as a coreceptor. If the individuals are homozygous for Delta-32, they are at less risk of becoming infected when exposed to HIV.<sup>59–61</sup> However, this protection is not absolute.

### SDF-1 GENE MUTATION

Individuals with the mutation of the gene producing a chemokine called stromal-derived factor 1 (SDF1) may be more resistant to infection. SDF1 is a cytokine that normally binds to the chemokine receptor CXCR4. The mutation may produce a limited level of SDF1, which in turn may affect the ability of HIV-1 to infect cells.<sup>62</sup>

### OTHER POTENTIAL COFACTORS

Some studies found an association between smoking and the more rapid rate of CD4+ lymphocyte loss or more rapid progression to disease. However, it was not supported by other studies.<sup>63,64</sup> Severe malnutrition, of the type observed in the developing countries, may accelerate HIV disease progression.<sup>65</sup> Whether milder forms of malnutrition play any significant role is less clear. Depression, stress, bereavement, and other psychological factors have not been shown to affect disease progression.

## Terminology of Untreated HIV Disease

### PROGRESSIVE GENERALIZED LYMPHADENOPATHY

The progressive generalized lymphadenopathy syndrome is a manifestation of an early stage HIV disease but without having any prognostic significance and specific implications. It must be

differentiated from lymphadenopathy caused by other disease processes, especially infectious diseases and lymphomas.

### AIDS-RELATED COMPLEX

The term AIDS-related complex (ARC) has been abandoned. We now know that the symptoms and signs labeled with the term ARC are manifestations of the middle stage of HIV disease. Hindsight revealed that ARC really means symptomatic HIV disease that does not qualify for the label of AIDS. Because the term ARC does not usefully locate a patient within the long continuum of middle stage disease; it is not useful in clinical management, as a case definition for reporting, or as a definable point for clinical studies.

### Acquired Immunodeficiency Syndrome (AIDS)

This syndrome is the last stage of HIV disease. Centers for Disease Control and Prevention (CDC) has subsequently revised its original case definition published in September 1982<sup>66</sup> to accommodate additional conditions recognized as manifestations of advanced HIV disease.<sup>67–71</sup> The term AIDS signifies the last stage of HIV disease in which immunodeficiency has become profound. However, advanced HIV disease is probably more descriptive. The 1987 CDC definition of AIDS continues to be useful to define an “end point” of HIV disease in clinical research and as criteria for case reporting that helps to quantify the growth of the epidemic of HIV disease. However, the criteria are irrelevant for the medical management of HIV disease, because an individual patient may not meet the criteria for AIDS as defined by CDC.

Following the introduction of highly active antiretroviral therapy; the concept of AIDS, as “end stage” immunodeficiency has become somewhat distorted. Highly active antiretroviral therapy can improve immunological function by boosting the CD4+ count and reducing the incidence of opportunistic infections whilst masking the remaining immune system deficits.

### Classification and Staging

Some system of nomenclature and classification is necessary to describe the progression of HIV disease through its stages in consistent and generally accepted terms. The CDC/World Health Organization (WHO) system that emphasizes the clinical presentation of HIV disease (Table 66.4 a and b)<sup>72,73</sup> is intended for “public health purposes, including disease reporting and surveillance, epidemiological studies, prevention and control activities, and public health policy planning epidemiological data”, but is of limited value for describing the progression of disease in an individual during clinical management or clinical research. Prior to 1996, when HIV RNA assays became widely available, clinicians used a combination of CD4+ counts and clinical signs for estimating stage and prognosis. There is as yet, no widely accepted standard formal system for the clinical staging of HIV disease.<sup>74</sup>

To characterize the disease in an individual, for the purpose of estimating prognosis, planning therapy and establishing criteria for enrolment or end points in clinical trials, the clinician would like to know how far the disease has progressed and how rapidly it is progressing. In untreated HIV disease, the former is currently most usefully indicated by the CD4+ count and the latter by the plasma HIV RNA level, usually termed as the “viral load.”

### Viral Load during HIV Infection: The Set Point

There is continuous viral replication from the time of initial infection until death. About 10 billion HIV virions are produced every day with a half-life of 6 hours in the plasma. CD4+ lymphocytes, which are one of the principal target cells responsible for viral replication, are also produced in high numbers and once infected will have a half-life of about 6 days. The life cycle of HIV infection from entry into one cell to the production of new progeny, which infect new cells, is about 2.6 days. Hence, there is an extraordinarily high level of viral replication, cell destruction and cell replacement.

HIV RNA becomes detectable in patient's blood within weeks of infection and precedes the appearance of HIV antigen and HIV antibodies. Over the following weeks, the level rises to a peak and then stays at a relatively stable level that is referred to as the set point (Fig. 66.5).<sup>75–78</sup> For an individual, this level is set to change relatively slowly over the following months or possibly years. The set point varies in different patients and its magnitude is related to the risk of disease progression. HIV viral load measurement is a major advance in HIV disease management and has two major applications, estimating the risk of progression (the prognosis) (Table 66.5) and monitoring the effectiveness of anti-HIV drug therapy. Studies prove a very strong correlation between the higher HIV viral load and the faster rate of progression of HIV disease.<sup>79–81</sup>

The HIV infected person will progress more or less sequentially through a series of characteristic clinical stages with the progressive depletion of CD4+ lymphocyte counts. The HIV infection can be divided into four stages:

1. Acute seroconversion illness or primary HIV infection
2. Asymptomatic stage of HIV infection
3. Early symptomatic stage of HIV infection
4. Late symptomatic and advanced stage of HIV infection (AIDS).

This clinical staging can be combined with a measure of immunodeficiency such as the total lymphocyte count (more than 2000, 1000–1999, and less than 1000 cells/ $\mu$ L) or, if available, CD4+ or T helper cell count (>500, 200–500, or <200/ $\mu$ L) to produce nine possible HIV stages (Table 66.6).

### STAGE 1: PRIMARY HIV INFECTION

Primary HIV infection (PHI) or acute HIV infection occurs before the antibody response. When the latter occurs, up to 90% of people may experience an acute seroconversion illness within 2–4 weeks of exposure. It usually resolves within 2 weeks and

**Table 66.4:** HIV Classification: CDC and WHO Staging Systems (July 2006; updated April 2009)

(a) CDC classification system for HIV-infected adults and adolescents				(b) WHO clinical staging of HIV/AIDS for adults and adolescents

**Fig. 66.5:** Virologic and immunologic course of HIV disease. Staging of HIV Infection.

may resemble glandular fever. Rarely, the illness may be quite prolonged and may merge into the later stages of HIV illness. Transient CD4<sup>+</sup> lymphopenia has been seen in the few patients studied.<sup>82</sup> At the time of PHI, there is always a high rate of viral replication leading to a transient rise in HIV viral load and concomitant immunosuppression due to a short-lived fall in the CD4<sup>+</sup> lymphocyte count. Sometimes the illness may be severe

**Table 66.5:** Correlation Between Viral Load and Survival Over Period of Time

HIV-1 RNA (/ml)	HTF-1 RNA (Log <sup>10</sup> )	Median time to AIDS (years)	% with AIDS at 6 years	Median survived (years)	% dead at 6 years
<500	<2.7	>10	5.4	>10	0.9
501–3000	2.7–3.47	>10	16.6	>10	6.3
3001–10,000	3.47–4.0	8.3	31.7	>10	8.1
10,000–30,000	4.0–4.47	5.5	55.2	7.5	34.9
>30,000	>4.47	2.8	80.0	4.4	69.5

with symptoms suggestive of AIDS, for example, oropharyngeal candidiasis and *Pneumocystis jirovecii* pneumonia. Diagnostic confusion as to the stage of HIV infection may arise, which can only be resolved by follow-up of the patient long enough to see the signs and symptoms resolve. HIV antibodies appear, the viral load falls and the CD4<sup>+</sup> count rises. A mild seroconversion illness may be missed if the clinician does not have a high index of suspicion and if a history indicating relevant risk behaviors or factors is not taken into account.

The appropriate diagnostic tests of PHI, which should be carried out on serial blood samples, includes a test for HIV antibodies. If this is negative and a primary HIV infection is suspected, then direct demonstration of viremia is necessary,

**Table 66.6:** Clinical Stages of HIV-1 Disease and Characteristics of Clinical Presentations with CD4<sup>+</sup> Cell Count Range

Stage of HIV disease	Clinical presentation	Usual CD4 <sup>+</sup> cell count/ $\mu$ L	Usual duration
Seroconversion illness/Primary HIV Infection (PHI)/Acute HIV infection	Fever, pharyngitis, rash, fatigue, mucocutaneous ulcers, lymphadenopathy, headaches, meningitis, encephalitis, neuropathies	150–800	3–14 days
Asymptomatic	Lymphadenopathy, headache	>300	2–10 days
Early symptomatic	Recurrent varicella zoster Oral candidiasis Seborrheic dermatitis Psoriasis Skin and nail infections (impetigo, folliculitis, fungal intertrigo, paronychia) Bacterial infections (pneumonia, bronchitis, sinusitis) Unexplained fatigue, fever, sweats, weight loss Diarrhoea Vaginal candidiasis Cervical dysplasia Cervical carcinoma <i>in situ</i> Recurrent pelvic inflammatory disease Tuberculosis	150–500	1–5 years
Late symptomatic	Kaposi's sarcoma Lymphoma <i>Pneumocystis carinii</i> pneumonia Toxoplasmosis Oesophageal candidiasis Cryptococcosis, cryptosporidiosis Recurrent herpes simplex virus HIV-I associated dementia complex Progressive multifocal leukoencephalopathy Tuberculosis	50–200	1–4 years
Advanced	Cytomegalovirus retinitis Cerebral lymphoma <i>Mycobacterium avium</i> complex infection (MAC)	<50	<2 years

using a p24 antigen (insensitive) or PCR. However, this is not available at all centers.

Lymphadenopathy typically appears in the second week of the PHI and may be generalized but preferentially affects the occipital, axillary, and cervical groups. Lymphadenopathy generally subsides in the majority of patients but may not completely resolve. A seroconversion illness associated with HIV-2 infection has also been reported.<sup>82</sup>

Treatment should be directed at alleviating any symptoms. There is considerable interest in the possible use of antiretroviral agents at this time. The virus may be more susceptible to treatment due to the relatively low numbers of virus particles that can replicate. The reduced ability of virus to infect a wide variety of cell types and the enhanced immune response seen in PHI renders the organism much more susceptible to treatment. The treatment could possibly prevent long-term damage to the immune system and delay or even prevent the development of AIDS.

## STAGE 2: ASYMPTOMATIC STAGE OF HIV INFECTION

Most HIV infected adults and children may expect to remain asymptomatic for many years following seroconversion. During this period, there are typically no abnormal findings on physical examination but the laboratory tests, related to HIV infection, are frequently abnormal. About 20–30% of people who develop lymphadenopathy during their seroconversion illness may have persistent generalized lymphadenopathy throughout the asymptomatic stage. Occasionally, people may experience headaches, which can be recurrent or chronic and debilitating in nature.<sup>83</sup>

CD4+ cell counts are usually within the normal range during the initial phase of the asymptomatic period. The rate of decline of the CD4+ cell count has been estimated as 84 cells per year for the first 4 years after seroconversion,<sup>84</sup> but enormous variations may occur among individuals and also within a single individual over time. The time between seroconversion and the development of early symptomatic disease has not been well-defined.

## STAGE 3: EARLY SYMPTOMATIC STAGE OF HIV INFECTION

Following infection with HIV, individuals may be entirely asymptomatic or may simply have enlarged lymph nodes with or without minor symptoms such as tiredness, lethargy, excessive sweating, and aches or pains in muscles or joints. The time between seroconversion and late symptomatic disease has been studied extensively and is estimated to be 11 years for homosexual men, with a possible variation in other HIV groups. Using statistical models, it has been projected that 76% of HIV infected people will develop late symptomatic disease by the year 16 of infection.<sup>85</sup> The rate of HIV-1 disease progression has been estimated to be three to four times greater than that of HIV-2.<sup>86</sup>

Through the early stage of HIV disease, the levels of virus detectable in the peripheral blood often remain low. However, this masks a very rapid rate of virus production and destruction in the lymphoid tissue.<sup>87</sup> The frequently observed generalized lymphadenopathy syndrome is probably a manifestation of this

process.<sup>88</sup> Many patients have painless, stable lymphadenopathy, which in some cases regresses as HIV disease advances, possibly because active HIV replication and immune destruction gradually destroy the architecture of lymph follicles. Anergy to skin testing becomes increasingly probable as the CD4+ count falls below 400/ $\mu$ L, with obvious implications for tuberculosis screening.

Common episodic conditions during this and later stages of disease include herpes zoster, *Candida*, seborrheic dermatitis, skin and nail infections like impetigo, folliculitis, fungal intertrigo, and paronychia along with bacterial infections like pneumonia, bronchitis, and sinusitis. Despite the relative scarcity of severe neutropenia in early HIV infection, bacterial sepsis is a major clinical problem that usually manifests as pneumonia, bacteremia or both. The incidence is 8–20 per 100 person years, depending on factors including location and risk activity. Recurrent herpes zoster is one of the earliest manifestations of symptomatic disease.

Oral candidiasis and oral hairy leukoplakia also occur but may not appear until a year after an episode of herpes zoster. Constitutional symptoms may occur for which no recognized cause is established by routine or specific investigations. These symptoms which include fatigue, fever, sweats, weight loss, and diarrhea occur relatively late in the stage of the disease. The pattern of occurrence and duration of constitutional symptoms varies greatly between individuals and their pathogenesis is likely to be a reflection of ongoing HIV replication and host immune response. Women may suffer from recurrent or persistent vaginal candidiasis. Moderate to severe cervical dysplasia or cervical carcinoma *in situ* are also clinical markers of early symptomatic disease in women. Pulmonary tuberculosis may occur in early or late symptomatic HIV disease.

Neurological manifestations including peripheral neuropathy and subtle manifestations of HIV dementia occasionally appear even in the early part of this period. Symptoms of peripheral neuropathy may persist, worsen, or in some cases, resolve as the disease progresses.

Dysregulation of the immune system leads to the proliferation of antibody producing B cells, hypergammaglobulinemia and occasional manifestations of autoantibody production such as immune thrombocytopenic purpura (although true purpura and bleeding are unusual) and prolonged partial thromboplastin time (lupus anticoagulant). As HIV disease advances and the immune system deteriorates, these manifestations often improve, presumably reflecting the decreasing ability to produce antibodies of any kind.

Isolated lesions of Kaposi sarcoma (KS) as opposed to extensive and rapidly progressive KS, may appear very early in HIV disease (CD4+ count > 500/ $\mu$ L). These early isolated KS lesions do not imply a poor prognosis. Isolated systemic non-Hodgkin lymphoma (NHL) lesions, but not central nervous system NHL, may occur in the middle stages of HIV disease.

Several of these clinical findings have been shown to be useful predictors of progression to late symptomatic disease but not independently of CD4+ cell counts. In one study of cohorts of homosexual men, the 2 years progression to AIDS for men with

herpes zoster, *Candida*, oral hairy leukoplakia, and constitutional symptoms were 25%, 39%, 42%, and 100%, respectively.<sup>60</sup> The predictive significance of the conditions exclusive to women has not been as well characterized as yet.

When the CD4+ count is about 350/ $\mu$ L, some general clinical manifestations such as bacterial pneumonias and sinusitis, occur with increased frequency but with usual clinical presentations and respond well to standard antibiotic regimens. As HIV disease progresses, uncommon presentation of non-HIV associated conditions including tuberculosis, incomplete response to standard courses of antibiotics, more severe and symptomatic clinical course of infections, reactivation of old infections held in check by the immune system like histoplasmosis, tuberculosis, and infection by uncommon pathogens become common.

#### STAGE 4: LATE SYMPTOMATIC AND ADVANCED STAGES OF HIV INFECTION (AIDS)

In the absence of treatment, the HIV infection progresses and the manifestations of late symptomatic disease typically appear when CD4+ counts fall below 200/ $\mu$ L. Opportunistic infections commonly occur. In the absence of prophylaxis, *Pneumocystis jirovecii* pneumonia is the most common and life-threatening infection. Malignancy, HIV dementia and profound constitutional symptoms such as fever, fatigue and weight loss are also hallmarks of late symptomatic disease.<sup>89</sup> Crowe et al. found that the order of appearance of opportunistic infections and malignancies during this stage was strongly correlated with the CD4+ lymphocyte count.<sup>90</sup> Only few opportunistic diseases occur when CD4+ cell counts fall just below 200 cells/ $\mu$ L, although tuberculosis, KS and progressive multifocal leukoencephalopathy are commonly seen. *Cryptosporidium* diarrhea is also a common problem, which is increasingly difficult to treat at this stage. Most of the individuals in the late stage tend to have anemia.

In advanced stage HIV disease, where CD4+ cell counts have fallen below 50/ $\mu$ L, CMV retinitis, *Mycobacterium avium* complex and primary cerebral lymphoma may occur, and HIV-1 associated dementia appears to progress more rapidly. Infections such as *Mycobacterium avium* complex, CMV, *Strongyloides stercoralis*, herpes zoster, or tuberculosis, that normally colonize superficially or are limited to an organ system or a local anatomic region, may invade other tissues or disseminate widely. Simultaneous, clinically significant infection by more than one pathogen is common. The 1987 definition of AIDS was modified in 1992 by the addition of three clinical conditions in the presence of HIV infection: cervical cancer, two episodes of bacterial pneumonia in 12 months, and pulmonary tuberculosis. Increasingly problematic are anorexia, nausea, vomiting, diarrhea, malabsorption, muscle wasting, and weakness.

Death eventually results from extensive disease of the vital organs, most commonly the lungs and presumably from the effects of circulating toxins, electrolyte abnormalities, hematopoietic and circulatory failure and autonomic nervous system damage. Approximately 50% of untreated patients die of infection within one year of the clinical diagnosis of acquired immune-

**Table 66.7:** Survival after Clinical Diagnosis of AIDS, Before Introduction of Effective Antiviral Therapy

Time	Survival (%)
1 yr	50
2 yrs	25
3–4 yrs	5
5 yrs	0

deficiency syndrome, while the chances of survival beyond 5 years have been reported to be nil (Table 66.7). Several of these opportunistic diseases have also been described in HIV-2 infected individuals.<sup>91</sup>

#### Summary

HIV is the causative agent of AIDS. HIV is transmitted primarily through sexual contact and hence genital mucosal surfaces are the portal of entry for HIV virus. HIV is a retrovirus which comprises a nucleoprotein core surrounded by other protein coats. The *pol* gene codes for the viral enzymes reverse transcriptase, integrase, and protease. Although HIV is one of the most recently discovered retrovirus, CD4 was the first retrovirus receptor to be identified. The HIV infection starts with the attachment of HIV through gp120 protein to the CD4 target cell. Virus entry into cells results from the fusion of viral and cell membranes, a process that depends on binding of virus *env* proteins to specific host-cell surface receptors. The HIV replication cycle comprises of two phases. The first phase involves the interaction between viral envelope proteins and specific host cell receptors (CD4 and CCR5/CXCR4) and the second phase involves the synthesis of viral RNA by RNA polymerase II using the integrated provirus as the template, followed by processing of the transcripts of the HIV genomic RNA.

It is well-established now that untreated HIV disease progresses relentlessly in almost all infected persons, from a clinically silent infection to severely damaged immunologic function resulting in the acquired immunodeficiency syndrome (AIDS). Following infection, the time before the onset of clinical disease varies from months to years. Various factors affect the progression of disease include viral and other cofactors, host factors defective co-receptors, SDF-1 gene mutations. There is overwhelming evidence to show that the host builds up immune responses against HIV. However the immune response against HIV is unable to eliminate the virus completely. Genetic traits that may affect progression more importantly include receptor mutations. The disease, if left untreated, leads to death over a median period of about 10 years. However, the time it takes to cover this spectrum varies greatly ranging from one year or less in some patients, to a still unknown upper limit in others. This upper limit has reached nearly 20 years in a few individuals called "long-term non-progressors." Long-term nonprogressors are rare individuals who are infected with HIV, but whose infection does not progress to AIDS. The duration is influenced by many different factors which may be primarily host related like the age and genetic makeup of the individual, but not by gender or mode of acquisition of the virus. Interaction between the host, HIV and environmental factors may determine the course of the disease, clinical manifestations and the rate of disease progression in each individual. Eventually, it causes death in most people. A high percentage of long-term nonprogressors have been shown to have inherited mutations of the CCR5 receptor of T cell lymphocytes. It is believed that the delta 32 variant of CCR5 impairs ability of HIV to infect cells and cause disease.

Various clinical syndromes may occur during the course of HIV disease. The untreated HIV disease can be classified into: Progressive generalized lymphadenopathy, AIDS-related complex, and AIDS, while various stages of disease are: acute seroconversion illness or primary HIV infection, asymptomatic stage of HIV infection, early symptomatic stage of HIV infection and, late symptomatic and advanced stage of HIV infection.

## HIV Diagnosis

Jessica Markby • Claire Ryan

### Introduction

Accurate diagnosis of HIV is crucial to appropriate patient care and management as well as population surveillance and screening programs. In the 1980s, the first available HIV diagnostic methods were all laboratory based, requiring centralized testing, specialized equipment, and a high degree of technical expertise. Currently, as well as improvements in the accuracy of laboratory-based testing algorithms, HIV testing has also evolved to enable point of care (POC) rapid testing. Fourth-generation rapid tests available today provide test accuracies equivalent to laboratory-based assays. This results in faster result turnaround times which enables both decentralization of testing and ensuring that patients actually receive their test results in a timely fashion. This has revolutionized HIV testing programs for developed countries as within specialized clinics results are now available rapidly at the point of testing, enabling appropriate clinical decision making. Similarly, in developing countries, the availability of rapid tests has meant that the logistical problems of specimen transportation and cold chain maintenance for test kits supply can be overcome and that testing can be made available in remote areas that are not serviced by higher tiered health facilities.

This section describes the scientific principles of HIV testing assays; both laboratory-based and rapid tests and describes commonly used HIV testing algorithms and quality assurance of HIV testing.

### Science of Human Immunodeficiency Virus

In order to appreciate the scientific principles of HIV testing methodology, it is first important to understand the basic science of HIV structure. HIV testing strategies target either specific components of the virus (proteins, glycoproteins, or RNA), or the products of the immune response to HIV (immunoglobulins/antibodies).

The HIV virus is simplistic in design comprising very few molecules. As depicted in Figure 67.1, the outer lipid membrane or envelope is embedded with two transmembrane glycoproteins: gp120 and gp41. Within this envelope layer is the nucleocapsid

**Fig. 67.1:** Schematic representation of the structure of HIV (<http://www.avert.org/hiv-virus.htm>).

or viral core, which is comprised of two layers of multimeric proteins; the outer most layer is comprised of the p17 protein and the inner layer of the p24 protein. Within this protein core the viral genomic information is contained as two single strands of RNA along with the viral encoded enzymes *reverse transcriptase* and *integrase*. The invasion and replication stages depicted in Figure 67.2 rely on these viral components.

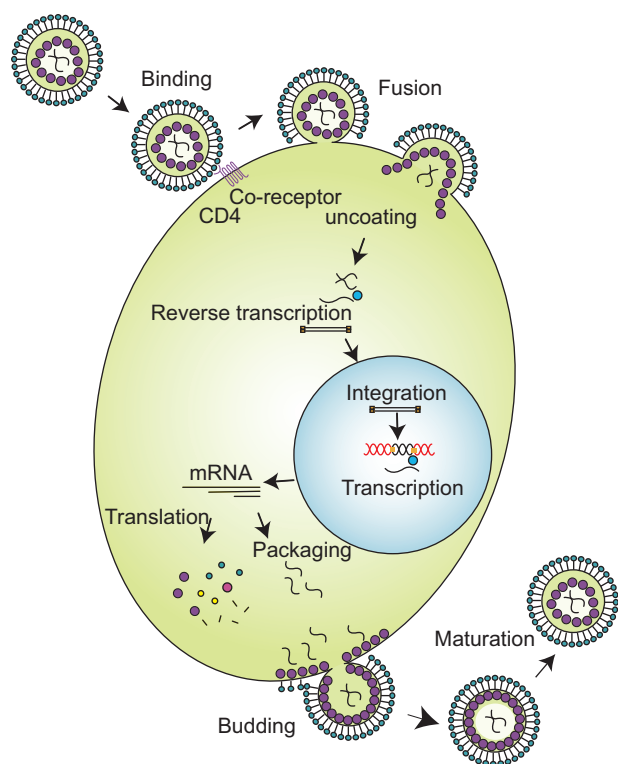

### Stages of HIV Infection and Immune Response

There are typically three phases of HIV infection which are characterized by distinct and measurable profiles of clinical indicators:

- Viremia
- Antibody production, and
- CD4 T lymphocytes levels.

One to 4 weeks after infection with HIV, symptoms of an acute illness develop in about 50–90% of individuals. This is associated with a rapid rise in plasma viremia to often several million copies

**Fig. 67.2:** Schematic representation of the HIV-1 infectious lifecycle. Binding, fusion, and entry are mediated by the interaction between the viral gp120 and host receptor CD4. The virus is uncoated in the cytoplasm prior to the reverse transcription of viral RNA into DNA. Following integration of the viral DNA into the host cell genome, transcription of the viral DNA occurs, before proteins are translated, processed and packaged into a virion which is able to bud from the cell surface, releasing mature virions. (Used with permission from Kate Jones, Burnet Institute, 2009.)

per mL and a concurrent depletion of CD4<sup>+</sup> T lymphocytes, causing patients to experience “flu-like” symptoms which can include fever, thrush, malaise, myalgia, swollen glands, diarrhea, and rash.

Within 7 days of infection, the adaptive immune response involving B lymphocytes, CD4<sup>+</sup> T lymphocytes, and cytotoxic CD8<sup>+</sup> T lymphocytes begins to mount an anti-HIV immune response. Antibodies to HIV however are not produced until around day 21–28 post infection and seroconversion is subsequently usually complete by 3 to 8 weeks post infection. Immunoglobulin (Ig) M is initially produced followed by IgG and IgA specific to HIV envelope glycoproteins gp41 and gp120, capsid and viral core proteins such as p17 and p24 as well as regulatory proteins. Following this acute phase of infection, there is a marked reduction from peak viremia to a viral load “set point”, usually within 6 to 9 months following infection. There follows a period of clinical latency, often referred to as asymptomatic chronic illness. In most untreated individuals, infection with HIV will ultimately lead to the development of AIDS, which is defined by the acquisition of opportunistic

**Fig. 67.3** The natural progression of HIV infection over time and the relationship between viral load and anti-HIV antibody production.

infections, and occurs due to the decline of CD4 T lymphocytes below a critical level and the significant impairment of cell mediated immunity.

As depicted in Figure 67.3 the viral load peaks during the acute stage of the infection while the antibody titer is low at undetectable levels during this window period of up to 3 months. This period of seroconversion is critical to determining the timing and selection of HIV testing assay given that all rapid tests, enzyme immunoassay (EIA), western blot (WB), and immunofluorescence assay (IFA) rely on the detection of anti-HIV antibodies. Therefore, false negative results are most likely to occur during this window period where patients remain seronegative.

## Principles of HIV Testing

HIV diagnostic tests can be broadly divided into two types: assays that measure anti-HIV antibody production or assays that measure components of the virus such as RNA, proviral DNA or viral proteins (such as p24) or in some cases a combination of the above.

### SEROLOGICAL METHODS

Serological assays for HIV diagnosis rely on the detection of antibodies produced against HIV derived proteins and are thus regarded as an indirect method of testing. Generally, serological assays use whole blood or dried blood spots (DBS) collected by venipuncture or skin prick, or blood fractions (plasma or serum) with variation from assay to assay. Some more recently developed serological assays utilize urine or saliva specimens making specimen collection less invasive.

The main problem associated with all serology based HIV assays is the inability to accurately diagnose during the window

period prior to seroconversion. Serological assay results can also be unreliable in advanced HIV infection where immune function is compromised and antibody titers to *pol* and *gag* are decreased and for diagnosis in infancy where maternal IgG (via the placenta) can mask the result.

## Laboratory-Based Methods

The first HIV diagnostic assays that were developed for use in laboratories were based on detection of anti-HIV antibodies and remain a mainstay for HIV diagnosis. Laboratory-based HIV tests include the EIA/enzyme-linked immunosorbent assay (ELISA), western blot (WB), and the immunofluorescence assay (IFA). EIA primarily detects IgG and uses indirect, sandwich, or competitive ELISA methodologies. As depicted in Figure 67.4, EIA typically employ kit based recombinant HIV antigens including p24, gp41, or gp120, which are covalently bound to a solid matrix (e.g., microwell plate). Patient serum or plasma is applied to the matrix and if positive, anti-HIV antibodies bind to their cognate well bound antigen. Subsequent addition of enzyme-conjugated anti-human monoclonal antibodies, followed by the enzyme substrate produces a colored product that can be measured colorimetrically. Examples of currently used, FDA approved or CE marked EIA include: Vironostika HIV-1 Plus O Microelisa System (which can also be used for DBS) and the Genetic Systems HIV-1/HIV-2. EIA requires between 60 minutes and several hours to run, as well as cold chain logistics and storage of reagents, specialized equipment and a higher degree of technical proficiency, making them generally unsuitable for smaller laboratories.

Western blot is commonly used to confirm positive EIA results in a traditional laboratory-based algorithm. Similar to EIA, WB detects patient antibodies to HIV using a suspension incubation of patient serum/plasma with a kit based HIV antigen to form an antigen-antibody complex. This complex is then subjected to gel electrophoresis which separates proteins according to size and charge over an electrical gradient. Proteins are then blotted from the gel onto a nitrocellulose membrane before the addition of secondary anti-HIV antibodies conjugated either to alkaline phosphatase or (more traditionally) a radioisotope. Protein bands are then visualized either by using autoradiography or substrate conversion into a colored product to detect HIV protein specific bands (refer to Fig. 67.5 for example). Similar to EIA, WB requires cold chain logistics and storage, expensive and assay specific equipment, and a high degree of technical expertise.

**Fig. 67.4:** Schematic representation of the principle of an EIA.

**Fig. 67.5:** Example of Western Blot band results. Lane 1: Negative control, Lane 2: Positive control, Lanes 3–10: Patient results over time since infection Day 0 to Day 30 ([www.hivinfosource.org](http://www.hivinfosource.org)).

WB has also been shown to produce a relatively high frequency (15–20%) of indeterminate results for negative specimens.<sup>1</sup>

The use of EIA for screening and WB for confirmation of patient samples results in a very high sensitivity 99.3–99.7% and specificity 99.7% if conducted after the window period. Within the window period, however, the sensitivity is significantly reduced.

A less common alternative confirmatory or supplementary test to WB is the IFA, which also relies on the detection of patient anti-HIV antibodies. Serum or plasma is incubated with immortalized human T cells that express HIV antigen on their cell membrane in association with MHC molecules. Next, the addition of a secondary antibody (anti-human antibody) that is conjugated to a Fluorescein isothiocyanate (FITC) molecule which emits green fluorescent light (518 nanometers) when excited with an ultraviolet light source (494 nanometers). This is then detected traditionally using microscopy (although it can also be detected and enumerated using flow cytometry). This system is employed in several laboratories in the USA. Specialized, expensive equipment, refrigeration, and a high degree of technical expertise are required for IFA and the process takes more than an hour and a half to complete. It is therefore only suited to low throughput testing facilities. IFA, such as the FDA approved Fluorognost HIV-1 assay, are equivalent in sensitivity and specificity to an EIA or a WB and may also be useful in determining the results from an indeterminate WB.

## Rapid Tests

When used in combination as a two or three rapid test algorithm, many currently available, FDA approved rapid test devices have comparable sensitivities, specificities, and predictive values to laboratory-based serological algorithms using EIA and WB. Rapid tests, which often generate results in 10–20 minutes, allow for a

much faster turnaround of results compared to laboratory-based assays and are therefore more suited to point of care testing. As patients do not need to return for results or be followed up by clinic staff, more patients are informed of their result. Several studies have shown that many patients do not return for results and those that know their results are more likely to change risk taking behaviors.<sup>2</sup> In addition, it provides the opportunity for clinicians to make decisions rapidly when an urgent result is required, such as in antenatal clinics, labor wards, and emergency blood product or organ donation. In addition, the ability to make quick decisions about post exposure prophylaxis requirements is possible using rapid test screening of blood products that present a risk of occupational exposure to HIV as well as in sexual assault cases. Rapid tests are generally also more cost effective than laboratory assays averaging around US\$ 2/test (ranging from US\$ 0.50 to 7.5). Additional advantages include the fact that they generally do not require highly trained personnel to complete and interpret the results and in most cases can be transported and stored at ambient temperatures. EIA and WB are not suitable for many small laboratories at provincial or district levels in developing countries where reliable power and water is often not available. Thus in developing countries, the introduction of rapid tests have enabled the decentralization of testing programs, which provide access to testing in even the most remote areas. In some countries, a single rapid test is used to screen patients using a highly sensitive rapid test. Initially reactive patients then require confirmatory testing, which is usually performed by sending a blood sample to a centralized laboratory. Other countries now confirm initially reactive results at the point of testing using a two or three rapid testing algorithm as described below.

There are six types of rapid tests described here defined by their mode of action; the first three of which are most commonly used for testing algorithms. Commonly used examples of each are listed in Table 67.1 illustrating their performance and operational characteristics. The first, most recently developed and most commonly used type of rapid tests, are collectively described as immunochromatographic or lateral flow assays. As depicted schematically in Figure 67.6, patient serum, plasma, or whole blood is applied to the specimen port or pad on the cassette or strip. The specimen then moves by capillary action along the nitrocellulose strip from the loading port to the detection port/window, which holds embedded HIV antigens (depending on

**Fig. 67.6:** Principle of immunochromatographic rapid tests.

**Fig. 67.7:** Example of an immunochromatographic rapid test. Stat-Pak HIV-1/2, illustrating positive (left) and negative (right) results (Adapted from WHO-CDC HIV Assays Operational Characteristics, Report 16 Rapid Assays).

assay these may be gp41 and/or gp120), which in several kits are conjugated to colloidal gold or selenium to facilitate visualization. A control line is also incorporated beyond the test line to ensure that the sample moves all the way through the strip. The control area is usually impregnated with anti-IgG antibodies conjugated to colloidal gold/selenium which bind to patient IgG forming a visual control line. An example of positive and negative results for a lateral flow device (Stat-Pak HIV-1/2) is shown in Figure 67.7.

Immunochromatographic assays are inexpensive (most are under US\$ 2 per test), only require 10–15 minutes for development of results and generally they do not require refrigeration. Most importantly, they are suitable for use in small laboratories or peripheral clinics/VCT sites as they do not require specialized equipment, do not require preparation of patient samples for serum or plasma, nor do they require a high degree of technical expertise to operate or read, and often require only a single step. Given that the results are read visually, there may be some subjective results particularly in the case of weakly reactive positives which may be false positives (higher in low prevalence areas) or early seroconverters. Examples of immunochromatographic rapid tests that are currently available include Determine HIV-1/2, Unigold HIV-1/2, Stat-Pak HIV1/2, OraQUick, HemaStrip HIV-1/2, Colloidal Gold, Sero Strip HIV-1/2.

The second type of rapid test is referred to as a particle agglutination-based test,<sup>3</sup> of which there are two formats. Both rely on the binding of anti-HIV antibodies in patient serum or plasma to HIV antigen covalently linked to latex or gelatin beads. Agglutination or cross-linking of antigen-bead complexes to the antibodies as depicted in Figure 67.8 can then be visualized as small solid particle clumping within a liquid medium. Some devices enhance agglutination by using narrow channels embedded in a clear plastic cassette through which the combined antigen/bead-antibody cocktails move through the cassette by capillary action and after 3–7 minutes, agglutination can be visualized as white clumps (e.g., Capillus HIV-1/2 refer to Fig. 67.8 for

**Fig. 67.8:** Photo of a particle agglutination HIV rapid test. Capillus HIV-1/2—(a) positive result; (b) negative result. Source: WHO-CDC HIV Assays Operational Characteristics, Report 16 Rapid Assays.

photograph of positive and negative results). Other particle agglutination rapid tests use microwell plate-based agglutination with antigen coated gelatin particles (e.g., Serodia HIV-1/2, MicroRED HIV-1/2). The latter are the least rapid and most technically demanding of all rapid tests and are only suitable for use by trained laboratory personnel. In addition, agglutination assay kits require refrigeration and cold chain logistics for reagents and difficulty has been reported widely for agglutination assays in determining whether weak agglutination reactions are positive or negative. Operator variability can be an issue.<sup>3</sup>

A third type of rapid test is known as membrane immunoconcentration devices and is also referred to as flow through assays. The patient specimen (plasma or serum although some can use whole blood) flows through solid phase capture technology using a porous membrane which contains immobilized HIV antigens conjugated to colloidal gold or selenium. The specimen is absorbed onto the membrane and the binding of anti-HIV antibodies to the antigen conjugate can be visualized as a line or dot in the membrane where immunobinding is focused. Several steps are often involved including specimen loading as well as conjugate and flow buffer addition. The whole assay takes between 5–15 minutes depending on the kit. Most kits require refrigeration, some differentiate between HIV-1 and 2 and most are more expensive than most immunochromatographic assays ranging from US\$ 4 to US\$ 8 per test.

A fourth and less commonly used HIV rapid test is the Immunodot EIA which incorporates solid phase HIV antigens fixed to teeth-like projections. In one example a mixture of three synthetic HIV antigens are used (two epitopes of gp41 and one gp120). The teeth are incubated in chamber wells containing diluted patient serum whereby anti-HIV antibodies are captured at the antigen containing binding site (clustered as a dot). Subsequent incubations that follow the sequence of a conventional EIA are then carried out as the card is moved between chambers containing secondary antibodies, conjugates and substrates. Upon completion, the teeth develop focused visual dots (usually purple) including control dots. Dots indicate HIV-1 and HIV-2 infection separately.

A fifth type of HIV rapid test is referred to as a red cell or hemagglutination assay and utilizes kit based HIV antigen complex to red blood cell protein antibody complexes. When added to the patient whole blood, the patients HIV antibodies cause agglutination of the patients red blood cells in less than 5 minutes if HIV positive.

A sixth type of HIV semi-rapid test category is the magnetic bead assays. An example of a magnetic bead assay is the Bionor HIV-1/2 which enables distinction of HIV-1 and HIV-2 and employs an ELISA-based methodology with magnetic beads as the solid matrix to which HIV antigens (gp41, gp120, gp36, and p24) are conjugated. The beads and bound patient antibodies are then separated using a magnet and subsequently ELISA-based colorimetric detection is carried out.<sup>4</sup>

## VIRUS PARTICLE DETECTION

The second major group of HIV diagnostic assays involves the *direct* detection of HIV particles either at the protein or the nucleic acid level. Direct HIV diagnostic assays include p24 antigen detection assays, nucleic acid-based assays, and cell culture assays. Direct detection methods allow earlier detection compared to serological methods as they do not rely on seroconversion for an accurate result. They therefore can be used during the window period with high sensitivities, often within 10 days of infection. They are also effective in testing immunocompromised AIDS patients and for early infant diagnosis. Unfortunately, most direct HIV diagnostic assays require a high degree of technical expertise to perform and are not suitable for small laboratories or lower tiered facilities. Specialized equipment is required for the assays and the tests are significantly more expensive than most serological assays. However, direct assays are widely used in centralized laboratories particularly in developed countries for confirmation of initially positive serology results as well as for early detection in adults and infants in both developed and developing settings.

### p24 Antigen Detection

The concentration of free HIV capsid antigen p24 in the blood increases to detectable levels between 1 and 3 weeks after HIV infection. Therefore, the p24 assay is suitable to use in individuals with recent exposure to HIV that may remain seronegative. Some p24 assays employ a sandwich ELISA-based assay to capture the p24 antigen in patient serum using kit based, plate bound, anti-p24 antibodies followed by subsequent addition of a secondary anti-p24 polyclonal antibody which is biotinylated enzyme (horseradish-peroxidase) conjugated to streptavidin, followed by substrate addition, thus enabling colorimetric detection and quantification.

Standard p24 ELISA assays have a sensitivity ranging from 10–60% depending on the assay with a lower limit of detection at 10 pg/ml. Thus in up to 60% of patients, p24 may not be detected. This is, in part, due to anti-p24 antibody production in patients which block binding sites on p24 resulting in the free p24 levels possibly being below assay detection levels. Modifications to this basic assay have been made to enhance its sensitivity thereby ensuring that the assay is suitable for diagnosis of seronegative patients as well as early infant diagnosis. These modifications include the addition of a heat denaturation step which releases p24 that is bound to anti-p24 antibodies in the patient blood

and a signal amplification step using the addition of a biotinyl tyramide reagent to increase the lower limit of detection (ELAST ELISA Amplification System). A further modification involves the simultaneous detection of HIV antibodies together with detection of p24 antigen. Dual assays are also referred to as fourth-generation assays and increase the sensitivity at earlier time points in the window period thus enabling detection reportedly 7 days earlier than standard serological assays.<sup>5</sup> They are therefore recommended in the United Kingdom as screening assays.<sup>6</sup>

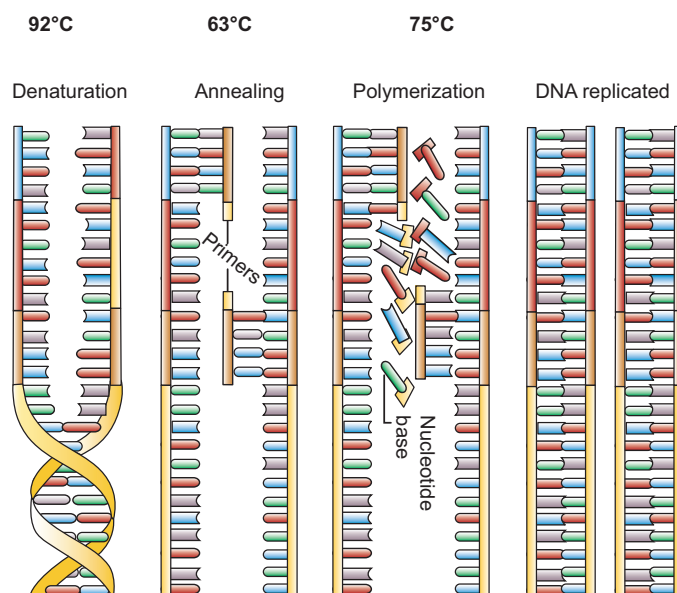

Most p24 assays are significantly less expensive than nucleic acid-based assays for HIV diagnosis. Additionally, they are generally simpler to perform and present a much lower risk of cross contamination and false positive results. Recently, a new rapid test for the detection of p24 has been developed with an incorporated magnetic immunochromatography/flow through device. Validation of this device by the Centers for Disease Control and Prevention (CDC) indicates promising performance results at lower costs to alternative p24 assays.<sup>7</sup>

## Nucleic Acid-Based Assays

Direct detection of HIV at early stages of infection is most commonly achieved using molecular assays that detect HIV nucleic acids. Nucleic acid-based assays detect specific HIV genes including the most conserved *gag* and *pol* sequences that are generally not the target of mutations. Molecular diagnosis of HIV can be performed both qualitatively and quantitatively and the use of these two methodologies is often interchangeable. Molecular diagnosis has generally been reserved for resource rich countries where qualitative or quantitative assays are commonly used for early detection of infection in adults (during the serological window period), routine infant diagnosis, in some laboratory algorithms as a supplementary or alternative assay to WB for confirmation of adult diagnosis as well as for routine use of quantitative assays for monitoring HIV patients for treatment candidacy and treatment efficacy. Due to the fact that these assays require specialized laboratory settings with expensive equipment, highly trained technicians, a high degree of quality assurance, and reagent costs are significantly higher than for serological methods; their use in resource-constrained settings has been limited. However, over the last 5 years an increasing number of developing countries have adopted molecular diagnostic assays where less expensive, non-molecular methods are not accurate such as for early infant diagnosis programs and in fewer cases for quantitative HIV patient treatment monitoring. In particular many developing countries in Africa, Latin America, and the Asia-Pacific region now routinely use molecular-based assays for diagnosis of HIV in early infancy.

### Qualitative Molecular Assays

The determination of HIV diagnosis using a qualitative molecular assay can be achieved using DNA or RNA-based methods. In the former, proviral HIV DNA typically within the *gag* or *pol* genes is amplified using a polymerase chain reaction (PCR). As depicted in Figure 67.9, extracted patient DNA/RNA is

**Fig. 67.9:** Three stages of a polymerase chain reaction. Denaturation, annealing and polymerization and typical temperatures used for cycling.

added to a master PCR mix containing deoxyribonucleotide triphosphates (dNTPs, monomeric nucleic acid bases), DNA polymerase (Taq), primers,  $MgCl_2$  and if appropriate reverse transcriptase (RT) enzyme for a RT-PCR. The PCR mix is then placed in a PCR machine which cycles between three key temperatures which correspond to DNA denaturation (unzipping of double stranded DNA), primer annealing (a short sequence of DNA complementary to single stranded target DNA binds), and polymerization (the addition of complementary dNTPs bind along the strand catalyzed by the polymerase). The result after one such cycle is the production of an identical copy of the target DNA. This process is repeated up to 30 times with a doubling or exponential increase in the amount of DNA with each cycle such that after 30 cycles the number of double stranded DNA molecules would be 1,073,741,824.

Amplified DNA product/amplicons can be detected using a variety of methods including detection of the amplified product by gel electrophoresis, real time fluorescence, or enzymatic/colorimetric visualization. Enzymatic/colorimetric detection is performed by hybridizing denatured, amplified DNA to microplate bound biotinylated probes followed by the addition of avidin-conjugated enzyme such as horseradish peroxidase, substrate is then added which results in a colored product that can be visualized and subjected to colorimetric analysis which may be qualitative or quantitative depending on the assay. Other qualitative PCR assays can also be used to detect different HIV subtypes and drug resistance mutations.

### Quantitative Molecular Assays

Quantitative assays also referred to as viral load assays are used in many developed settings for HIV diagnosis confirmation but their

capabilities make them specifically suitable for quantifying HIV for the purposes of monitoring HIV patients for viral progression. As with qualitative PCR, viral load can be used for HIV diagnosis as a confirmatory assay for patients that test positive with an HIV screening assay and are often used as a supplementary or confirmatory assay in place of WB or IFA. Viral load assays can be used for early diagnosis of adult infection during the window period and for early infant diagnosis as a substitute for conventional qualitative PCR. Viral load however is regarded as the standard of care for monitoring HIV patients in developed countries, but remains relatively rare in developing countries. Its use however, is expanding, particularly with the growing body of evidence for inaccuracies in immunological-based monitoring<sup>8,9</sup> as well as the cost ineffectiveness of not using viral load monitoring on public health expenditures is made more evident.<sup>10</sup>

The quantity of virus is expressed as copies of virus (usually RNA) per mL of plasma or alternatively as international units (IU) per mL. Variability of viral load readings is common from day to day for one patient and from assay to assay hence the importance of looking at trends and multiple readings. The main methods used for viral load assays for which FDA approved diagnostic kits are available are reverse transcription (RT) PCR previously described (e.g., Amplicor [Roche]), branched DNA PCR (e.g., Versant [Bayer]) which does not involve amplification but rather a series of hybridization and probe based capture of target sequences and subsequent enzymatic visualization<sup>11</sup> and nucleic acid sequence-based amplification (NASBA, e.g., Nuclisens [BioMérieux] which amplifies RNA using a PCR at a single temperature using multiple primers and enzymes, making it more rapid reviewed in).<sup>12</sup> Each type of assay requires assay specific equipment including in some cases automated robots components (e.g., Roche Ampliprep).

The development of fluorescence-based detection assays, in particular real time PCR which utilizes fluorescent dyes such as SYBR green and Taqman probes enables highly accurate quantification of double stranded DNA products in a PCR. Typically in a real time PCR assay, fluorescence resonance energy transfer (FRET) is employed whereby two fluorescent dyes one of high energy (reporter) and one of low energy (quencher) are conjugated to the 5' end and 3' end of the probe. The energy is transferred from high to low (reporter to quencher) emitting a low energy when the two dyes are in close proximity to one another and the probe is intact. However, as DNA polymerization occurs, the probe which is designed to sit between the forward and reverse primers is cleaved by the DNA polymerase enzyme when it encounters the probe at the end of polymerization. This cleavage of the probe causes separation of the reporter and quencher, which alters the energy and wavelength of light emitted. The higher energy now being emitted from the reporter can be detected and recorded with each PCR cycle enabling real time quantification of PCR products by way of fluorescent enumeration. Real time PCR is less susceptible to cross contamination due to a closed tube system, however it requires specialized equipment and relatively expensive reagents. It is used in developed countries for early HIV diagnosis

or confirmation as well as viral load monitoring in developed and more recently in some developing countries as an alternative to conventional quantitative PCR techniques described previously.

### ***Pediatric Diagnosis using Nucleic Acid Testing***

Antibody tests commonly used for adult HIV diagnosis are not reliable for diagnosis of HIV exposed infants under 18 months due to the fact that maternal HIV antibodies may still be present in the child, (maternal anti-HIV IgG crosses the placenta), creating the need for additional methods of testing. Without anti-retroviral therapy (ART), 20–45% of HIV-infected women transmit the virus to their infants. There is a high risk of death before 2 years of age among HIV-infected infants. Given the increased availability of ART in resource-constrained settings, the World Health Organization (WHO) recommends that early infant virological testing (EID) be carried out in order to allow initiation of ART for HIV-positive infants.<sup>13</sup> EID enables identification of HIV-positive infants in order to provide appropriate and early treatment and care, reducing infant morbidity and mortality. In addition, in the case of HIV-negative infants, EID also enables for early decisions around prevention, including alternative infant feeding options.

Although several DNA and RNA-based assays can be used for infant diagnosis, the most widely used and validated method, which is endorsed by the CDC and WHO as the most suitable assay for the early diagnosis of HIV in infants and FDA approved by the US, is a qualitative HIV DNA PCR (Roche Amplicor version 1.5) assay using whole peripheral blood.<sup>14</sup> Proviral HIV DNA is isolated from the nucleus of peripheral blood leukocytes. More recently, this assay has been adapted for use with whole DBS, making it more suitable for countries with constrained cold chain logistics networks.<sup>15,16</sup> Molecular diagnosis of infants in the first month of life shows a very high sensitivity and specificity using the gold standard Roche Amplicor 1.5 reaching 98% and 100%, respectively<sup>17</sup> and reaching 100% at 2 months of age.<sup>18</sup> The Roche Amplicor HIV DNA PCR is relatively expensive at approximately US\$ 24 per test and requires a high degree of technical expertise, time (each run requires about 6 hours), specialized equipment, and quality control.

### **Cell Culture**

Diagnosis of HIV using cell culture is not commonly used, especially in light of the ease of use, speed, and accuracy of results obtained from serological and direct virus detection assays described previously. However, virus isolation can be achieved by co-culturing patients' peripheral mononuclear cells with healthy donor leukocytes or T-cell lines (indicator cells). HIV in patient mononuclear cells can be detected by changes in the indicator cells in culture; however due to the long time required to culture cells (greater than 2 weeks), it is generally not used for diagnosis of HIV infection but rather than for characterization of the virus including analyses of drug resistance profiles using for example quantitative plaque reduction assays.

## Impact of Genetic Diversity on HIV Testing

There are two distinct types of HIV—HIV type 1 (HIV-1) and HIV type 2 (HIV-2). HIV-1 is the most widespread, and is responsible for the majority of infections worldwide. HIV-2 infections are generally restricted to certain geographical areas, namely Western Africa and Western India. HIV-1 can be further divided into three main groups termed group M (main), group O (outlier), and group N (non-M and Non-O). Group M viruses are the most widespread, and in turn are divided into nine different subtypes (A, B, C, D, F, G, H, J, K) and a number of different recombinant forms which result from the recombination of two or more subtypes. As serological tests target antibodies specific to HIV, or HIV antigen, they are far less subject to the genetic diversity displayed by HIV than nucleic acid-based tests, which target specific sequences within a reasonably conserved HIV gene.

As nucleic acid-based tests are predominantly used for confirmation purposes, or for early infant diagnosis, the clinical indications of HIV must be taken into consideration in a diagnosis. The majority of the issues that arise as a result of HIV genetic diversity concern HIV monitoring, in particular, HIV viral load testing.

## HIV Testing Algorithms

An algorithm refers to the combination and specific sequence of assays used in a testing strategy. In HIV diagnosis there are many variations of testing algorithms used in different countries and also within countries depending on the setting and use. For example, different testing algorithms may be used for blood screening for transfusion, HIV screening at Voluntary Counseling and Testing (VCT) sites, antenatal clinics, and for HIV surveillance/research. The positive predictive value (PPV) (or likelihood of a positive test result being correct using a single test) is dependent on the HIV prevalence. With a decrease in HIV prevalence, PPV also decreases (e.g., HIV prevalence of 10% confers a PPV of 97%, but at a prevalence of 2% the PPV is 87% using Uni-Gold rapid test).<sup>19</sup> Sequential testing using two or three rapid tests in series or parallel, however, has been shown to be significantly more sensitive and specific with higher positive and negative predictive values (approaching 100% depending on the assays used). As previously mentioned, some testing algorithms involve laboratory-based testing, others employ rapid testing which can be carried out at the point of care/testing, and others involve both point of care screening and laboratory-based assay confirmation. Testing algorithms may be done in parallel where all tests in the algorithm are carried out simultaneously or by serial testing where the first test is used as a screening test and if it is positive then subsequent confirmatory/supplementary tests are used. In resource constrained settings, serial testing is common as it offers a more cost effective approach. Some of the key factors considered when testing algorithms are developed include individual test performance indicator data (specificity, sensitivity, and positive and negative predictive values specific to each setting dependent of HIV prevalence), as well as indicators for tests when used in combination and sequence in an algorithm, test availability within countries including approval labeling, ease of

use, cost, storage conditions for test reagents, equipment required, training of personnel required, specimen type, and the potential to differentiate between HIV-1 and HIV-2.

Tests in an algorithm should not share the same false positives and negatives. Generally speaking, an HIV-positive diagnosis is dependent on the concurrence of at least two positive assay results. When the results from these two tests do not agree the result is referred to as discordant, indeterminate or inconclusive. In such cases, a third assay may be employed as a “tie-breaker”, or alternatively, the patient may be requested to return again after 2 or more weeks (or after the window period) for follow-up testing. Indeterminate results may be caused by the patient being in the window period and exhibiting seronegativity for less sensitive assays. Alternatively, indeterminate results may be caused by assay inaccuracies including false positives or negatives.

Historically, a single EIA was first used in 1985 for screening donated blood. Following this, VCT centers were established and blood was sent to laboratories for testing using EIA. The occurrence of false positives (particularly in low prevalence areas) led to the need to develop a two-test algorithm by the CDC in 1989. The first use of a two test algorithm was the laboratory-based EIA followed by either a WB or IFA. This became the gold standard globally. Patients typically waited 1–2 weeks for results in developed countries and much longer in developing countries. This greatly reduces the number of patients who learned their results due to patients being lost to follow-up. Even moderate waiting times (107 minutes) for results can lead to up to 55% of patients not waiting to receive their results compared to shorter times resulting in significantly more patients receiving their results.<sup>20</sup>

Currently there are many algorithms in use globally, however in 2009 the CDC issued a report on HIV testing algorithms which outlines several specific testing algorithms for point of contact (POC) testing and laboratory testing.<sup>19</sup> The report outlines four POC algorithms which use assays that are simple and rapid without blood preparation and that can enable results reporting at the same visit. The first algorithm, developed in 2004, is designed to screen out negative patients at the POC and refer initially positive specimens for laboratory confirmation. It is a combined POC screening using a single rapid test on blood; and for reactive specimens distinct confirmatory assay(s) are carried out. The second POC algorithm employs two different sequential rapid tests on blood. The third POC algorithm is a variation on algorithm 2, as it involves screening using oral specimen with one assay, followed by confirmation for initially reactive specimens using blood with a second assay. The fourth POC algorithm involves three different rapid tests performed sequentially and is suited to low resources settings where higher tiered laboratories are not available/accessible. The third test is employed as a “tie-breaker” if the results from the first two tests do not agree. Laboratory-based algorithms involve assays that include a combination of rapid tests or more complex assays that require blood preparation. They are used for a variety of purposes depending on the setting and use and include screening as well as confirmatory testing of POC reactive specimens.

## Quality Assurance

Quality assurance (QA) is a vital component of HIV diagnosis whether using POC and/or laboratory-based algorithms. It is essential to ensure that the HIV testing process has been carried out properly and that the kit reagents are performing as intended. Although FDA approved and validated assays provide highly reliable results, there is always potential for human error in testing and recording of test results. A comprehensive QA program for HIV testing is therefore vital to provide identification of potential mistakes and to reduce or prevent ongoing errors. Essential components of a comprehensive QA program for HIV testing include appropriate training, supervision, and assessment of testing personnel as well as provisions of written instructions typically in the form of standard operating procedures are crucial preparatory measures for quality assured HIV testing. In addition, the provision of appropriate test kits, reagents and consumables that are standardized, approved and validated need to be used and controlled for stock management. An appropriate and safe environment for testing must also be provided. Documentation of testing activities is also an important component of quality control in order to trace potential sources of error or confusion. During the testing practice there are several practical measures of quality control that should be employed as part of quality assured HIV testing including internal and external controls. External quality assessment schemes (EQAS) are also an important component of QA for HIV testing and should be carried out on a regular basis using an established program.<sup>19</sup>

### Summary

In this chapter, we have illustrated the key principles of HIV diagnosis as well as the practical aspects of achieving accurate results in clinical practice. Understanding the structural and functional molecular components of HIV as well as the kinetics of the immune response to HIV infection is critical to understanding how diagnostic assays are designed to work. Indirect diagnostic assays or serological assays rely on the detection of anti-HIV antibodies and have been designed for use both in the laboratory and more recently in clinical or field-based diagnostic settings. There are many different serological HIV diagnostic assay formats that rely on different test principles including Western blotting, immunochromatography/concentration, immunoprecipitation, particle agglutination, and immunofluorescence. Direct diagnostic assays, however, detect the presence of HIV viral particles either at the protein (e.g., p24) or nucleic acid level (RNA or DNA). Accurate early pediatric diagnosis requires direct viral particle detection due to the fact that maternal anti-HIV antibodies may be present in the circulation of the infant even if the HIV virus has not been transmitted. In practice, a clinical/laboratory testing algorithm is required that employs more than one assay. This involves the combination of two or more tests that use different testing principles (e.g., EIA and Western blot), and which offer an increased, combined sensitivity and specificity. A myriad of different testing algorithms are used globally with various combinations of assays, which differ in different settings/purposes such as blood donor screening, labor wards or voluntary counselling and testing. Regardless of the algorithm used, robust quality assurance of HIV testing is an integral component of ensuring accurate results are provided to the patients to determine appropriate HIV interventions and care.

## Pharmacology of Antiretroviral Drugs

Tara McGinty • Patrick W.G. Mallon

### Introduction

The introduction of the first antiretroviral agent, zidovudine, in March 1987 heralded a new era for those who were suffering from HIV infection. The early 1990s saw monotherapy as the standard of care but initial hopes of effective HIV management were short-lived as patients experienced treatment failure.<sup>1</sup> In 1995, the results of the European-Australian DELTA Study and the American ACTG 175 Study demonstrated the superior efficacy of dual NRTI therapy over monotherapy in reducing AIDS defining illnesses and death.<sup>2-4</sup> The introduction of HIV RNA quantification techniques offered an objective measure of antiviral efficacy and opened broader insights into relationships between pharmacokinetic and pharmacodynamic properties of antiretroviral drugs and their efficacy. In 1997, protease inhibitors were developed following elucidation of the molecular structure of HIV protease and their use in combination with other antiretroviral agents gave rise to the term Highly Active Antiretroviral Therapy (HAART).<sup>5,6</sup> Since then, numerous additional antiretroviral agents and at least three new classes of antiretroviral drugs have been added to the list of agents available for the management of HIV (Fig. 68.1, Table 68.1). In areas with access to the therapy, HIV is now considered as treatable chronic illness with viral suppression achievable even in heavily pretreated patients.

The availability of such a variety of agents that can be used in multiple different combinations gives rise to many potential pharmacokinetic (PK) and pharmacodynamic (PD) interactions. Hence, it is necessary to understand the mechanisms of action as well as the PK and PD characteristics of commonly used antiretroviral agents to gain maximum durable benefit and make appropriate drug choices for patients. This chapter provides a basic overview of the pharmacokinetic and pharmacodynamic principles relevant to the antiretroviral medications and summarizes the currently available antiretroviral agents, including their mechanisms of action, basic pharmacology, toxicities, and important drug interactions. The role of Therapeutic Drug Monitoring (TDM) in clinical practice and potential new agents

in development is also discussed. As this chapter cannot cover all aspects of pharmacology in a therapeutic field that develops as rapidly as HIV, internet references for information sources on drug prescribing and interactions are provided at the end of the chapter.

### Life Cycle of HIV

The HIV life cycle, understanding of which has been pivotal to the development of the 6 currently used antiretroviral drug classes,

1987	Zidovudine (AZT)
1991	Didanosine (ddI)
1992	Zalcitabine (ddC)
1994	Stavudine (d4T)
1995	Lamivudine (3TC), Saquinavir (SQV)
1996	Ritonavir (RIT), Indinavir (IDV), Nevirapine (NVP)
1997	Nelfinavir (NFV), Delavirdine (DLV), 3TC/ZDV (Combivir - CBV)
1998	Efavirenz (EFV), Abacavir (ABC)
1999	Amprenavir (APV)
2000	Lopinavir/ritonavir (kaletra), Trizivir (ZDV/3TC/ABC)
2001	Tenofovir (TDF)
2002	
2003	Enfuvirtide (ENF), Atazanavir (ATV), Emtricitabine (FTC), Fosamprenavir
2004	ABC/3TC (Kivexa), TDF/FTC (Truvada)
2005	
2006	Darunavir (DRV), TDF/FTC/EFV (Atripla)
2007	Raltegravir (RAL), Maraviroc (MVC)
2008	Etravirine (ETR)

**Fig. 68.1:** Timelines for licensing of antiretroviral agents for treatment of HIV-1 infection. Figure describes the year of licensing of each antiretroviral with the generic drug name followed by commonly used mnemonic in parentheses.

**Table 68.1:** Currently Available Antiretroviral Medications and Drug Classes

NRTI	NNRTI	Protease inhibitors	Integrase inhibitors	Maturation inhibitors	Fusion inhibitors
Zidovudine	Nevirapine	Saquinavir	Raltegravir	Maraviroc	Enfuvirtide
Didanosine	Delavirdine*	Ritonavir			
Stavudine**	Efavirenz	Indinavir			
Lamivudine	Etravirine	Nelfinavir			
Abacavir		Lopinavir/ritonavir			
Tenofovir		Atazanavir			
Emtricitabine		Fosamprenavir			
Zalcitabine* (discontinued)		Tipranavir			
		Darunavir			

\*Discontinued.

\*\*Discontinuation recommended by WHO.

NRTI, nucleoside reverse transcriptase inhibitor; NNRTI, non-nucleoside reverse transcriptase inhibitor.

can be broadly classified into 11 different stages, 5 of which are targets for antiretroviral agents.

**Attachment:** Interactions between the viral envelope protein gp120 and the CD4 receptor, expressed on T-cells, macrophages, monocytes and dendritic cells, cause a conformational change in the host cell membrane exposing the beta-chemokine receptors CXCR4 or CCR5. The third variable (V3) loop of gp120 binds to these chemokine receptors, with differences in V3 loop determining the affinity of circulating virus for either the CCR5 or CXCR4 receptors—termed CCR5 or CXCR4 tropism. Determination of tropism classifies an individual's virus as being CCR5-tropic, CXCR4 tropic or mixed tropic, depending on the relative affinity of the virus for these receptors in cell-based infectivity assays or based on genotype sequences of the V3 loop sequence of gp120 that can predict viral tropism. Binding to both the CD4 receptor and these chemokine co-receptors results in change in the virion structure to allow direct contact between the viral envelope and the host cell membrane. Maraviroc, a CCR5 antagonist, binds to cellular CCR5 co-receptors and prevents attachment of CCR5-tropic virus and is used as an antiretroviral agent in patients with CCR5-tropic virus.<sup>7</sup>

**Fusion:** Another viral envelope protein, GP41, facilitates fusion between the viral envelope and cell membrane through interactions between two repeat sequences in the gp41 peptide known as heptad 1 and heptad 2. This interaction leads to collapse of the extracellular portion of gp41 envelope allowing fusion. Enfuvirtide, a fusion inhibitor, is a synthetic peptide derived from the heptad 2 sequence, which competitively binds to heptad 1, prevents change in gp41 and therefore inhibits fusion.<sup>8</sup>

**Reverse Transcription:** Fusion between the viral and host cell membranes allows delivery of the viral core into the host cell cytoplasm. Shedding of the viral capsule P24 protein exposes single-stranded viral RNA, which is transcribed to single-stranded complementary DNA (cDNA) by HIV reverse transcriptase. After DNA-dependent polymerase creates double-stranded DNA from this cDNA template, viral reverse transcriptase then uses its ribonuclease activity to degrade viral RNA. Two classes

of antiretrovirals have been developed to target HIV reverse transcriptase.<sup>9</sup>

Nucleoside reverse transcriptase inhibitors (NRTI) are analogs of the naturally occurring deoxynucleotides; thymidine, adenosine, guanosine, cytosine and cytidine (Table 68.2). All NRTIs undergo intracellular phosphorylation by cellular kinases to their active triphosphate forms. During viral reverse transcription, they compete for incorporation in expanding viral DNA chains. All NRTI compounds lack a 3'-hydroxyl group on the deoxyribose moiety, which prevents further addition of nucleotides to the growing DNA chain, causing chain termination and thereby inhibiting viral replication.

In contrast, the non-nucleoside reverse transcriptase inhibitors (NNRTI) bind to a nonactive site on HIV reverse transcriptase, competitively inhibiting the enzyme and preventing the normal movement of the protein domains required for DNA synthesis.

**Integration:** Integration of transcribed viral DNA into the host genome is mediated by the viral integrase enzyme, a 32kDa protein encoded by the integrase portion of the viral *pol* gene. HIV integrase consists of three domains: an N-terminal zinc finger domain that enhances multimerization and promotes

**Table 68.2:** Reverse Transcriptase Inhibitors Classified by Target Nucleotide Analog

Class	Purine		Pyrimidine	
	Adenosine	Guanine	Cytosine	Thymidine
Endogenous nucleotide				
Synthetic NRTI analogs	Didanosine (ddI)	Abacavir (ABC) (carbovir)	Zalcitabine (ddC)	Zidovudine (AZT)
	Adefovir (PMEA)		Lamivudine (3TC)	Stavudine (d4T)
	Tenofovir disoproxil fumarate (TDF)		Emtricitabine (FTC)	

integration of the two ends of viral DNA into the host cell chromosome, a dimeric central catalytic domain that is required for the enzymatic activity of HIV integrase, and a C-terminal domain that directs DNA binding.

Integrase binds to the viral DNA, creating a preintegration complex, and cleaves two nucleotides from the 3'-hydroxyl end of the viral DNA, exposing active chain ends. This preintegration complex then migrates to the host cell nucleus where HIV integrase cleaves the host DNA allowing the host and viral DNA to bond, resulting in strand transfer of the viral DNA into the host genome. Raltegravir is an HIV integrase inhibitor that interrupts integrase activity by binding to the catalytic domain and preventing strand transfer.<sup>10</sup>

**Virion Assembly and Maturation:** After integration, HIV provirus may lie latent within cells or undergo transcription into messenger RNA. At present, there is no effective treatment to remove latent virus from within cells and it therefore serves as a reservoir for persistent infection. Once a cell begins active viral RNA transcription, distinct splicing patterns result in either multiply-spliced variants that are transcribed into the regulatory proteins *nef*, *tat*, and *rev*, or single, unspliced transcripts which are either transcribed into the structural and enzymatic transcripts *pol* and *gag* or remain untranscribed to form new viral RNA particles. Together with host cell factors, these various components assemble into mature virions that are released from infected cells. These virions remain non-infectious until *gag* protein is cleaved into constituent proteins including the p24 capsid protein by the HIV protease, which infers infectivity on the virion. The HIV protease is an aspartyl protease and is a target for the protease inhibitor class of antiretroviral drugs, which bind to the active site of the HIV protease, disabling the enzyme and rendering virions noninfectious.<sup>11,12</sup>

## General Principles of Pharmacokinetics and Pharmacodynamics

In order to understand pharmacological issues specific to antiretroviral agents and particularly their use in combination, it is useful to review basic principles of pharmacology.

### PHARMACOKINETICS

Pharmacokinetics describes interactions between the host and a drug, principally related to processes of absorption, distribution, metabolism, clearance, and elimination. Exploration of these processes provides information relating to the bioavailability of the drug, the degree of protein-binding and the volume of distribution, the peak and trough drug concentrations in the blood (i.e., the  $C_{\max}$  and  $C_{\min}$  values), and the elimination half-life ( $t_{1/2}$ ) of the drug as well as the total systemic exposure to a particular drug estimated from the area under the concentration/time curve (AUC).

After oral administration, absorption of a drug depends on factors such as the drug formulation, gastric pH and emptying, gastrointestinal motility, perfusion of the absorptive surface

and the expression of transporters in the enteric surface such as P-glycoprotein. Different formulations of the same medication can result in significantly differing pharmacokinetics, as illustrated by the protease inhibitor lopinavir/ritonavir. Initially a soft gelatin capsule given as three capsules twice daily (BID) (133/33 mg) required dosing with food, but this when changed to a melt extrusion tablet formulation and taken two tablets BID (200/50 mg) showed sufficient increases in  $C_{\max}$  and AUC and lessened the need for dosing with food.<sup>13</sup>

Gastric pH is also important in the absorption of certain antiretrovirals, particularly the protease inhibitor atazanavir, the AUC of which is decreased by more than 75% in the presence of proton pump inhibitors and therefore, should not be coadministered.<sup>14</sup>

The volume of distribution is the relationship between the total amount of drug in the body and its concentration in the plasma and it is defined as the total amount of drug in the body/plasma concentration of the drug. The volume of distribution is influenced by the extent of plasma protein-binding and by physiological states. An increase in body fluid volume resulting from renal failure and a decrease in plasma proteins seen in liver failure can both increase the volume of distribution, while it is decreased with excess fluid loss seen with burns or with dehydration.

Protein-binding of drugs, to either albumin or  $\alpha$ -1-acid glycoprotein, involves complex interactions whereby the bound drug is slowly released from the binding protein at a rate determined by several physiological and competitive processes, including presence of other drugs competing for binding to the same protein. As only the unbound active free drug can cross through biological membranes reaching target receptors or be available for renal elimination, altered protein-binding may affect the therapeutic action of drugs or significantly alter its elimination half-life. Protein-binding varies significantly with antiretrovirals with the non-nucleoside reverse transcriptase inhibitors being highly protein bound.

### Pharmacokinetic Drug Concentration: Time Curve

Important pharmacokinetic parameters are estimated by measuring the concentration of the drug at various time points during the dosing schedule (Fig. 68.2). The peak drug concentration reached following drug administration is termed the  $C_{\max}$  and corresponding time is termed  $T_{\max}$ . Both parameters are intrinsically governed by the rate of drug absorption. After reaching the  $C_{\max}$ , the concentration of the drug gradually declines, with the elimination half-life ( $t_{1/2}$ ) being the time taken for the plasma drug concentration to fall by 50%. Most drugs follow "first-order" kinetics, where the rate of elimination is constant over time (Fig. 68.2). Mathematically the elimination half-life is determined by both the volume of distribution ( $V_d$ ) and the clearance (Cl) with the relationship defined by the equation  $t_{1/2} = 0.693 \times V_d / \text{Cl}$ . Changes in either the clearance or the volume

**Fig. 68.2:** The pharmacokinetic concentration: time curve.  $C_{\min}$  = minimum plasma concentration;  $C_{\max}$  = maximum plasma concentration.  $T_{\max}$  = time to reach maximum concentration;  $t_{1/2}$  = elimination half-life, estimated as the time for the drug concentration to fall by 50% during the elimination phase (provided that drug metabolism follows first-order kinetics;  $IC_{50}$  = concentration of drug required to inhibit 50% of viral replication in vitro. With the majority of antiretroviral medications it is desirable to re-dose before the plasma concentration of the drug reaches the  $IC_{50}$ .

of distribution of a drug may result in a significant change in the elimination  $t_{1/2}$ . Total body clearance is the volume of plasma cleared per unit time and is a function of the dose and the area under the concentration:time curve (dose/AUC).<sup>15</sup>

The “area under the curve” (AUC) of the concentration/time curve provides an indication of the bioavailability of a drug. As such, this can be altered by changing the dose, absorption or clearance of a drug. As a drug is cleared, the concentration will fall to a level at which redosing should occur. This concentration is termed the  $C_{\min}$  and is the minimum concentration in the dosing interval. This usually occurs prior to the subsequent dose although, depending on absorption properties of the drug, the concentration may continue to fall for a short time after administration of the next dose before adequate absorption occurs. Pharmacokinetic characteristics of commonly used antiretroviral agents are outlined in Table 68.3.

As many pharmacokinetic properties of drugs involve interactions with biological systems, there is unsurprisingly significant inter-individual variability in drug concentrations, arising from differences in absorption, distribution, metabolism and elimination between individuals. The contribution of host genetics to these processes is increasingly recognized. Pharmacogenomics may help explain some extreme variability within certain individuals, mostly exhibited through genetic

variations in cytochrome P450 (CYP450) isozyme metabolism arising from the presence of particular polymorphisms that may predispose an individual to either accelerated or reduced drug metabolism.

## PHARMACODYNAMICS

Pharmacodynamics describes the effect of the drug on the body. It is the relation between drug concentration and the pharmacological response in terms of efficacy. It also relates to drug concentration and the related toxic side effects. The desired range of concentration of a drug should produce effect without toxicity and is termed as the therapeutic range.

## Pharmacokinetics, Pharmacodynamics, and Antiretrovirals

In order to maintain constant suppression of viral replication, a sufficient plasma concentration of an antiretroviral must be sustained throughout the dosing interval. It is therefore important, particularly for drugs such as protease inhibitors and non-nucleoside reverse transcriptase inhibitors, that the  $C_{\min}$  never falls below a concentration required to maintain virological suppression. The concentration of drug necessary to suppress 90% or 95% of viral replication (the  $IC_{95}$ ) is estimated *in vitro*. During periods of nonadherence, or if drug interactions result in increased clearance of an antiretroviral drug, the  $C_{\min}$  may fall sufficiently to permit viral replication to recur, which can lead to treatment failure (termed virological failure) and the emergence of resistance (see below).

A significant number of antiretroviral agents undergo hepatic metabolism and induction or inhibition of the hepatic CYP450 enzyme system by PI, NNRTI and the CCR5 antagonist maraviroc may result in drug–drug interaction when used in combination. The specific isozymes affected by each drug are outlined in Table 68.4. Induction of the CYP450 enzyme systems increase plasma concentrations of the isoenzymes resulting in decrease in the plasma concentration of substrate drugs. The integrase inhibitor raltegravir is somewhat different as it is metabolized by the uridine diphosphate-glucuronosyl transferase A1 enzyme (UGT A1). Most NRTIs are renally eliminated, hence the lower propensity for drug–drug interactions within this class. The exceptions are zidovudine, which is metabolized via glucuronidation with minimal renal elimination, and the nucleotide RTI (NtRTI) tenofovir, which is actively secreted from renal tubular cells.

Enzyme induction can take up to 14 days to take effect. This complicates use of drugs which induce their own metabolism, such as the NNRTI nevirapine, which is therefore initiated at a lower dose for 2 weeks to enable enzyme induction after which a higher maintenance dose is required to maintain therapeutic plasma concentrations and antiviral efficacy.<sup>16</sup> In contrast, inhibition results in decreased metabolism and elimination of the substrate drug and results in prolonged  $t_{1/2}$ . The protease inhibitor ritonavir is a potent inhibitor of the CYP3A4 isoenzyme. This

**Table 68.4:** Antiretroviral Agents and Enzymes Involved in Their Transport and Metabolism

Drug class	Drug	Substrate	Inhibition	Induction
NNRTI	Efavirenz	3A4, 2B6		3A4, 2B6
	Etravirine	3A4, 2C9, 2C19	2C9, 2C19	3A4
	Nevirapine	3A4, 2B6		3A4
Protease inhibitor	Atazanavir	3A4, P-gp	UGT 1A1, 1A2, 3A4	
	Fosamprenavir	3A4, P-gp	3A4 ( <i>in vitro</i> )	3A4 ( <i>in vivo</i> )
	Darunavir	3A4, P-gp	3A4	
	Indinavir	3A4, P-gp	3A4	
	Lopinavir/ritonavir	3A4, P-gp	3A4	2C9, 2C19, 1A2
	Nelfinavir	2C19 (M8 → 3A4)	3A4	
	Ritonavir	3A4		
	Saquinavir	3A4, P-gp	3A4	
	Tipranavir		3A4, 2D6	1A2, 2C19
NtRTI	Tenofovir	MRP4		
Integrase inhibitor	Raltegravir	UGT 1A1		
CCR5 inhibitor	Maraviroc	3A4		

MRP4, multidrug resistance protein type 4; NtRTI, nucleotide reverse transcriptase inhibitor; NNRTI, non-nucleoside reverse transcriptase inhibitor; P-gp, Transmembrane drug transporter P-glycoprotein; UGT, uridine diphosphate-glucuronosyl transferase. Other substrate codes denote isoenzymes of cytochrome P450 system. All parameters are derived from relevant drug product information booklets.

characteristic has been manipulated to increase the bioavailability of most other protease inhibitors by combining them with a small dose (baby dose) of ritonavir. By inhibiting metabolism, ritonavir increases the drug concentrations throughout a large dosing interval, thereby enabling lower pill burden and easier dosing schedule.<sup>17</sup>

Antiretroviral pharmacodynamics is complicated by the fact that the efficacy of most antiretrovirals is not measured directly through inhibition of a target viral enzyme, but indirectly through inhibition of viral replication. The main pharmacodynamic metrics in HIV therapy for efficacy are the HIV RNA quantification (either *in vitro* or *in vivo*) and increases in CD4 + T lymphocytes. Pharmacodynamic properties are further complicated by the fact that the antiretroviral drugs are used in combination, rendering it more difficult to determine the relevant pharmacodynamic properties of individual drugs within a combination. As a result, few clear dose–response relationships have been described for antiretrovirals. Similarly, as toxicities arising from antiretroviral exposure often do not relate to effects on inhibition of the target enzyme, but rather arise from non-antiviral effects of antiretrovirals on host biological processes (such as development of hepatic, renal,

or bone marrow dysfunction), these toxicities vary considerably and are often not related to either the dose or pharmacokinetic properties of the antiretrovirals. As a result, the utility of routine measurement of antiretroviral pharmacokinetic properties as part of routine care in HIV-infected patients is questionable.

However, pharmacokinetic and pharmacodynamic properties of antiretrovirals determine not only their effectiveness but also their propensity to cause virological failure and induce resistance in the setting of low-plasma drug concentrations. The potential for antiretroviral drugs to induce resistance upon treatment failure, particularly failure to first-line antiretroviral therapy, differs considerably between antiretroviral drug classes. These differences can be explained at least in part by the pharmacokinetic and pharmacodynamic characteristics of specific drugs.<sup>18</sup>

## HIV AND ANTIRETROVIRAL RESISTANCE

The high-replication rate of the HIV virus, (an estimated  $10^{10}$  copies of HIV virus is produced per day in the absence of suppressive therapy), together with a high-error rate during replication, leads to multiple mutations occurring during replication. Some of these mutations occur in genes that are targets of antiretroviral therapy (such as the reverse transcriptase gene) and may alter the amino acid sequence of the resulting protein, which can in turn alter the ability of the drug to inhibit the replication.<sup>19</sup> For example, a mutation in HIV reverse transcriptase gene that results in an amino acid substitution of methionine for valine at position 184 (M184V) enables a virus with this mutation to continue to replicate even in the presence of the NRTI lamivudine (3TC). This “replicative advantage” means that, in the presence of lamivudine alone, virus with M184V mutation will be able to replicate while wild-type virus will remain suppressed.<sup>20</sup>

Resistance can be measured in three main ways: using genotypic assays, phenotypic assays, or a combination of the two—the virtual phenotype. In the genotype test, HIV RNA is derived from plasma of a patient with suspected resistance and the sequence of the gene of interest is compared to the sequence of “wild-type” or fully sensitive virus. Genes commonly examined include sequences of the *pol* gene that encode HIV reverse transcriptase and HIV protease, and the *env* gene encoding the V3 loop of gp120. Presence of particular mutations will give rise to changes in amino acid composition of the resulting protein, which can result in resistance to a particular antiretroviral drug. By mapping these mutations, a genotypic assay can help predict drugs to which the virus has developed resistance or is still sensitive.<sup>21</sup>

A phenotypic assay involves culturing of a virus with particular resistance mutations and exposing it to individual antiretrovirals in order to determine if the drugs can inhibit viral replication and, if there is a reduced activity, what fold increase in  $IC_{50}$  is required to overcome resistance. This test has the advantage of being able to quantify the level of resistance induced by a particular mutation but has the disadvantage of taking a considerable time to perform and also being expensive.

The virtual phenotype relies on comparing viruses with known mutations or groups of mutations to a database of phenotypic

test results of viruses known to harbor these mutations. This assay is much cheaper and, as it is comparative, is much quicker to perform than a phenotype test, but is dependent on the availability of archived data on the phenotypic characteristics of the virus under investigation.

With continued exposure to a drug, over a period the resistant virus will emerge as the predominant viral strain, leading ultimately to treatment failure. Emergence of resistance is prevented by using multiple drugs in combination, thereby making it more difficult for the virus to produce an increasing number of mutations required to render it resistant to multiple antiretroviral medications, and by ensuring that the concentrations of the drugs do not fall below a threshold where there is selective pressure on viruses harboring resistance mutations to replicate and become the predominant circulating viral species.<sup>22</sup> The range of drug concentrations in which resistant virus can replicate whilst wild-type virus remains suppressed is termed the “zone of selective pressure” (Fig. 68.3).

## ANTIRETROVIRAL RESISTANCE AND PHARMACOKINETICS

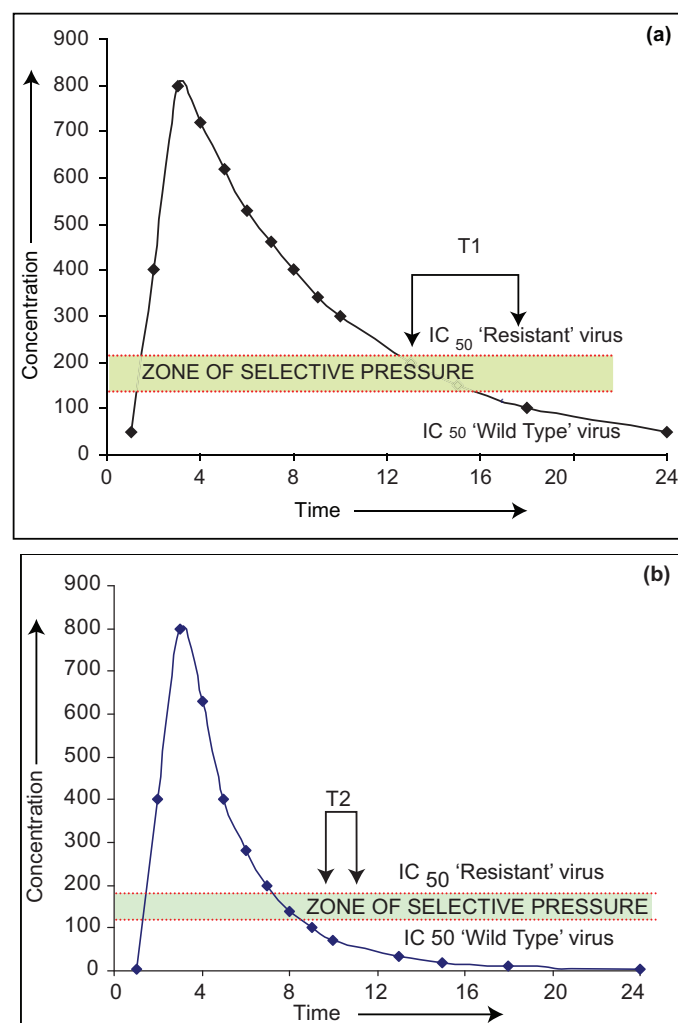

The pharmacokinetic properties of certain antiretrovirals may help explain the relative risk of resistance developing when drug concentrations fall. Patients failing antiretroviral regimens-containing drugs with longer half-lives, such as the NNRTI drug class and the integrase inhibitor raltegravir (Table 68.3), in which less resistance mutations are required to result in high-level resistance (termed a “lower genetic barrier” to resistance), tend to fail with drug resistance when compared to patients failing antiretroviral regimens-containing drugs with short half-lives and those that require multiple resistance mutations before high-level resistance occurs (a “high genetic barrier”), such as protease inhibitors.<sup>18</sup>

**Fig. 68.3:** Antiretroviral pharmacodynamics and resistance. The  $IC_{50}$  of a virus harboring resistance mutations may be higher than that of a wild-type virus, providing the resistant virus with a replicative advantage over the wild-type virus in conditions where the plasma concentration of an antiretroviral lies above that necessary to inhibit wild-type virus but below that necessary to inhibit resistant virus. This range of concentrations is termed the *zone of selective pressure*.

This is because with the use of drugs with short half-lives and high genetic barriers, the time during which the drug concentration remains within the zone of selective pressure remains short (Fig. 68.4a), so there is less time for the virus to develop the resistance mutations necessary to render the virus resistant and provide it with a replicative advantage over the wild-type virus. In contrast, in drugs with the longer half-lives and a lower genetic barrier, the time spent within the zone of selective pressure is considerably longer, giving more time for resistant mutations to arise while the wild-type virus remains suppressed (Fig. 68.4b). This is reflected in the higher number of patients failing NNRTI- or integrase-containing HAART with viruses harboring resistance mutations compared to patients failing ritonavir-boosted protease inhibitor-containing antiretroviral regimens.<sup>19,23</sup>

**Fig. 68.4:** Antiretroviral pharmacodynamics, elimination half-life and resistance. If taken intermittently, the plasma concentrations of drugs with longer elimination half-lives (a), such as non-nucleoside reverse transcriptase inhibitors and integrase inhibitors, spend more time in the 'zone of selective pressure' than drugs with shorter elimination half-lives (b), such as protease inhibitors, providing more opportunity for resistance mutations to emerge.

## ANTIRETROVIRAL RESISTANCE AND PHARMACODYNAMICS

Specific resistance mutations can result in very different changes in drug pharmacodynamics. The amount of additional drug required to suppress replication in a resistant virus (termed the "fold increase" in  $IC_{50}$  compared to wild-type virus) can vary greatly. The inhibitory quotient (IQ) provides a way to link this pharmacodynamic property to the pharmacokinetics of the specific drug. The IQ is the ratio between the  $C_{min}$  and the  $IC_{50}$  of either the wild-type or resistant virus ( $C_{min}/IC_{50}$ ), with a correction for protein-binding applied to translate *in vitro*-derived  $IC_{50}$  or  $IC_{95}$  values to *in vivo* drug concentrations (correction factor =  $IC_{50}/[\text{fraction free drug in vivo}]$ ).<sup>24</sup>

The inhibitory quotient can be very useful when presence of one or more mutations results in small, or step-wise increases in the fold change of the  $IC_{50}$  compared to wild type. Such an effect is seen with use of protease inhibitors, in which baseline IQ has been associated with subsequent virological response to therapy in treatment experienced patients, with a higher IQ expected to result in better drug potency. However, for drugs such as non-nucleoside reverse transcriptase inhibitors, where presence of single mutations can result in dramatic increases in  $IC_{50}$  (for example the K103N mutation is associated with a 20-fold increase in the  $IC_{50}$  of efavirenz), the clinical utility of the IQ is less clear, as the increase in drug necessary to suppress the resistant virus is not realistic at clinically used doses.

Two variations of the IQ have been used in clinical research: the virtual inhibitory quotient (VIQ) and the normalized inhibitory quotient (NIQ). The VIQ is calculated for by dividing a patient's  $C_{min}$  by the expected fold change in viral susceptibility (FC) obtained from a virtual phenotype of the virus under investigation, multiplied by the serum-adjusted control wild-type viral  $IC_{50}$  value ( $C_{min}/[FC \times IC_{50}]$ ) and the NIQ is derived by dividing an individual's IQ for a specific virus to the population IQ.<sup>25,26</sup> Both of these variations attempt to provide a more robust relationship between pharmacodynamics and pharmacokinetics for antiretroviral drugs and shown limited predictive value in determining treatment response to antiretroviral therapy, particularly in heavily pre-treated patients with resistant viruses.<sup>27</sup>

As the IQ relies on the  $C_{min}$  as the only pharmacokinetic parameter, this estimate presumes that inhibition of virological replication does not appreciably change at higher antiretroviral drug concentrations. However, *in vitro* research suggests that there is a dose-response relationship between antiretroviral drug concentration and the ability of HIV to infect new cells, that can be graphically depicted in a dose-response graph. The slope of this graph can be used to determine the instantaneous inhibitory potential (IIP) of an antiretroviral drug at specific concentrations, defined as the log reduction in single round infectivity at clinically relevant drug concentrations. For example, the IIP for  $C_{max}$  is derived from the equation,  $IIP_{C_{max}} = \log(1 + (C_{max}/IC_{50})^m)$ . Like the IQ, this equation incorporates both pharmacodynamic (the slope parameter "m" of the *in*

*vitro* dose–response curve and the  $IC_{50}$ ) and pharmacokinetic ( $C_{min}$ ) parameters (formula  $[IIPx = \log(1 + Cx/IC_{50})m]$ , where  $x$  = specific drug concentration). The IIP can potentially explain the superior performance of several antiretroviral drugs such as the PI atazanavir and darunavir and the NNRTI efavirenz in clinical trials, as they maintain an  $IIPC_{max}$  at 24 hours well above ( $>5 \log$ ) that required for viral inhibition.<sup>28,29</sup> However, which of the three measures described best predicts response still remains to be determined.

## Specific Antiretroviral Classes and Agents

This section provides a more detailed description of the currently available antiretroviral drug classes and the commonly used drugs within each class, outlining their mechanism of action, pharmacokinetic properties, adverse reactions, long-term toxicities, and important drug interactions.

### NUCLEOSIDE REVERSE TRANSCRIPTASE INHIBITORS

The NRTIs are synthetic analogs of naturally occurring purine and pyrimidine analogs which act by competitive inhibition of HIV1 reverse transcriptase. With the exception of tenofovir disoproxil fumarate (TDF), the NRTIs are actually prodrugs requiring intracellular activation via a three-step phosphorylation

process that converts them to their active triphosphate form.<sup>30</sup> The *nucleotide* reverse transcriptase inhibitor TDF requires only two-step phosphorylation for activation. As previously described, HIV reverse transcriptase cannot distinguish NRTI triphosphates from their naturally occurring counterparts and their incorporation into growing viral DNA results in chain termination. Dual NRTI therapy, which forms the backbone of conventional HAART, comprises two agents related to differing purine or pyrimidine bases so as to avoid two drugs competing for incorporation for the same target base (Table 68.2). NRTIs also have the potential to inhibit host cellular DNA polymerases, including the mitochondrial DNA polymerase gamma (DNA pol-gamma). Tissue-specific inhibition of DNA pol-gamma by NRTI has been postulated to underlie many of the medium and long-term toxicities observed with NRTI use.

All the available NRTIs are available in oral formulations with oral bioavailability ranging from 25% to 90%. As only intracellular phosphorylated drugs are active, dosing schedules are not generally designed around the elimination half-life (Table 68.3). In general, plasma concentrations of NRTIs do not correlate with antiviral efficacy or toxicity as it is the rate of phosphorylation of the drug that is thought to determine activity.<sup>31</sup> Table 68.5 shows pharmacokinetic and pharmacodynamic characteristics of the available agents in the NRTI class.<sup>33–39</sup>

**Table 68.5:** Pharmacokinetic, Pharmacodynamic, and Treatment Characteristics of NRTI

Agent	Plasma $t_{1/2}$	Intracellular $t_{1/2}$	Oral bioavailability	Elimination	CSF:Plasma ratio	Common dosing	Comment
Zidovudine (AZT)	1.1	3	60%	Glucuronidation and renal excretion	0.5	300 mg BID	Toxicities include anemia and lipoatrophy
Didanosine (ddI)	1.6	25–40	30–40%	Renal excretion	0.21	Daily	Toxicities include lactic acidosis and lipoatrophy Use in combination with tenofovir results in lower CD4 <sup>+</sup> T-cell responses and higher virological failure rates
Stavudine (d4T)	1.0	3.5	85%	Renal excretion	0.39	40 mg BID	Linked with lipoatrophy, lactic acidosis, and peripheral neuropathy Dose reduction recommended if weight < 60 kg
Lamivudine (3TC)	3–6	12	83%	Renal excretion	0.12	Daily/ BID	FDC when combined with AZT
Abacavir (ABC)	1.5	24–60	83%	Metabolized by alcohol dehydrogenase and glucoronyl transferase Renal excretion of metabolite	0.3–0.44	Daily/ BID	Hypersensitivity in 4%—increased in HLA B*5701 positive recipients Linked with increased risk of myocardial infarction in some studies FDC when combined with 3TC Additional FDC when combined with both 3TC and AZT
Tenofovir disoproxil fumarate (TDF)	17	10–50	25–40% High-fat meal	Renal glomerular elimination and active tubular secretion	0.04 <sup>32</sup>	Daily	Can accumulate in renal tubular cells Rarely may cause renal failure, proteinuria, and Fanconi syndrome
Emtricitabine (FTC)	10	20	93%	Renal excretion	0.43	Daily	FDC when combined with TDF

BID, twice daily dosing; FDC, fixed-dose combination;  $t_{1/2}$ , elimination half-life; CSF, cerebrospinal fluid.

## Zidovudine

Zidovudine received approval from the US Food and Drug Administration (FDA) for treatment of HIV-1 infection in adults in 1987 and in infants over 3 months in 1990. It is available in several formulations, such as liquid (10 mg/ml), tablets (300 mg), capsule (100 mg), and suspension for IV injection (10 mg/ml). Zidovudine is metabolized by hepatic conjugation to an inactive glucuronidated metabolite and undergoes renal elimination, with clearance greatly exceeding creatinine clearance, indicating that significant tubular secretion takes place. Both renal and hepatic impairment may affect clearance of zidovudine.<sup>33</sup>

Zidovudine is effective in decreasing mother-to-child transmission (MTCT) of HIV. In the PACTG-076 study, maternal treatment with zidovudine during pregnancy and labor, and newborn administration in the first 6 weeks of life decreases MTCT by 70%. In neonates, zidovudine elimination is slower immediately after birth and then increases dramatically after the first week of life. This is important particularly in premature neonates when dosages must be decreased due to greatly decreased elimination.<sup>40</sup>

In addition to mitochondrial toxicity (discussed below), zidovudine may cause anemia secondary to bone marrow suppression. This can be a treatment limiting toxicity in some patients and is particularly problematic in resource limited settings where there is a high prevalence of helminth infection, which can also cause chronic anemia.<sup>41</sup>

## Lamivudine

Lamivudine is the negative enantiomer of a synthetic cytidine analog. In addition to anti-HIV-1 activity, it also has activity against HIV-2 and hepatitis B infection. It is available in liquid (10 mg/ml) and tablet (150 mg) formulations. Lamivudine is predominantly (70%) cleared unchanged in the urine, with clearance partly age dependant with dosages decreased in the first week of life. Lamivudine concentrations are increased in patients with moderate to severe renal impairment due to decreased clearance. Lamivudine pharmacokinetics are not significantly affected by hepatic dysfunction.<sup>42</sup>

## Tenofovir Disoproxil Fumarate

As tenofovir disoproxil fumarate (TDF) is a nucleotide, it bypasses the initial rate-limiting phosphorylation step and is hydrolyzed by plasma esterases and then metabolized intracellularly to the active triphosphate form. It is available in 300 mg tablets. Its oral bioavailability is affected by coadministration with a high-fat meal with a 40% increase in AUC. Pediatric dosing studies have shown  $C_{max}$  and AUC values decreased by up to 30% in children taking adult capsules. Due to the anionic charge of the molecule, it is thought to have poor CSF penetration.<sup>36</sup>

Elimination of TDF is predominantly renal, with active renal tubular secretion via renal transport proteins OAT 1 and 3 and MRP4. In patients with renal failure, TDF can accumulate in renal

tubular cells and can rarely induce renal failure with a Fanconi's-type proximal tubulopathy (characterized by hypophosphatemia, proteinuria, aminoaciduria, and glycosuria) in patients without known pre-existing renal dysfunction.<sup>43</sup> Regular monitoring of renal function (creatinine clearance and dipstick urinalysis) is recommended for patients on TDF. Pharmacokinetics of TDF are not substantially altered in subjects with hepatic impairment.

## Emtricitabine

Emtricitabine (FTC) is a fluorinated analog of lamivudine, although it does have a longer elimination  $t_{1/2}$  than lamivudine and is available as a capsule (200 mg) and oral solution (10 mg/mL). Its longer half-life supports once-daily dosing, which has resulted in its use in fixed-dose combination (FDC) form with TDF (Truvada®) and with TDF and efavirenz (Atripla®). Like lamivudine, FTC is ineffective in viruses harboring a resistance mutation M184V/I in the reverse transcriptase gene, although the frequency of the M184V mutation in patients on FTC is lower than that seen in patients failing lamivudine-containing regimens.<sup>21</sup>

## Abacavir

Abacavir is a carbocyclic nucleoside available in liquid (20 mg/ml) and tablet (300 mg) formulations. It has a relatively high CSF:plasma ratio suggesting good CSF penetration with potential use in patients with HIV-associated central nervous system (CNS) disease. It is primarily metabolized by hepatic glucuronidation and carboxylation. It is a substrate for P-glycoprotein and undergoes hepatic metabolism, although avoiding the CYP system. However, its metabolism may be affected in patients with moderate to severe hepatic impairment. Use of abacavir has been linked to the development of a hypersensitivity reaction (HSR), which occurs predominantly in patients carrying the HLAB\*5701 allele (see section on Antiretroviral Toxicities below).<sup>35</sup>

## NON-NUCLEOSIDE REVERSE TRANSCRIPTASE INHIBITORS

This class of drugs can be roughly classified into the first generation NNRTIs, efavirenz, nevirapine, and delavirdine (an older NNRTI which is no longer in use) and the second generation NNRTIs, etravirine and rilpivirine (TMC278, which is still in clinical trials). NNRTIs bind non-competitively to the p66 subunit of HIV-1 reverse transcriptase at a hydrophobic pocket distant to the active site of the enzyme, inducing a conformational change that alters the active site, decreasing the ability of naturally occurring nucleotides to bind. This inhibits cDNA elongation and halts viral replication.

Although effective, first generation NNRTIs have a low genetic barrier to resistance, and cross-resistance to all first generation NNRTIs can result from the presence of a number of single mutations in HIV reverse transcriptase. The second generation NNRTIs retain antiviral activity in the presence of some of these mutations, although their efficacy decreases considerably

**Table 68.6:** Pharmacokinetic, Pharmacodynamic, and Treatment Characteristics of NNRTI<sup>16,44–47</sup>

Drug	Plasma $t_{1/2}$	Oral bioavailability	CSF:Plasma ratio	Dosing	Comment
Efavirenz	45	/a	0.61	600 mg/day	Available as FDC with TDF and emtricitabine (Atripla®) Associated with CNS side effects
Nevirapine	25–30	93%	0.63	200 mg BID or 400 mg/day	Can cause hepatotoxicity when initiated with high CD4 <sup>+</sup> T-cell counts Rash common
Etravirine	41	Not established	No data	200 mg BID	Less interactions with methadone Significant interactions with some protease inhibitors and maraviroc

BID, twice daily dosing; FDC, fixed-dose combination;  $t_{1/2}$ , elimination half-life; CSF, cerebrospinal fluid.

with accumulation of NNRTI-resistant mutations. Etravirine, in particular, is a highly flexible molecule and may alter or rotate within the binding site to allow multiple-binding conformations in the presence of pre-existing resistance mutations.<sup>9</sup>

Both efavirenz and nevirapine induce the hepatic CYP 450 system, giving rise to multiple potential drug–drug interactions. NNRTIs are generally heavily protein bound but have good CNS penetration (Table 68.6).<sup>16,44–47</sup>

## Efavirenz

Efavirenz is recommended in first-line HAART regimens for ARV-naïve patients in most treatment guidelines.<sup>48</sup> Like the other NNRTIs, it has an extended elimination half-life (Table 68.3) favoring once-daily dosing. Although it is highly protein bound (approximately 99%), the free fraction penetrates the CSF with a CSF/plasma ratio of 0.61. Efavirenz undergoes hepatic elimination predominantly via CYP2B6 and to a lesser extent through CYP3A4 metabolism. The AUC is significantly increased (28%) when dosed with high-fat meals; therefore, it is recommended to be taken on an empty stomach.<sup>44</sup>

Efavirenz induces CYP3A4 metabolism and can therefore interact with drugs metabolized via this pathway. It also induces its own metabolism, with steady state pharmacokinetics reached after approximately 14 days therapy. As it undergoes hepatic metabolism, efavirenz should be used with caution in patients with mild to moderate liver disease and is contraindicated in patients with severe hepatic impairment. As less than 1% of efavirenz is excreted unchanged in the urine, the impact of renal impairment on efavirenz elimination should be minimal. Its use in pregnancy is controversial, as first trimester exposure in animals was associated with development of neural tube defects.<sup>44</sup>

Although rash is commonly observed after initiation of efavirenz, it is often mild and may resolve without discontinuing treatment. Rarely severe rash will occur, necessitating treatment discontinuation. The principal toxicity of efavirenz is in the central nervous system (CNS), with symptoms ranging from insomnia, dizziness and vivid dreams to frank psychosis and depression. These side effects are most prevalent within the first 2 weeks after treatment initiation, probably reflecting higher circulating plasma concentrations in the days preceding full

auto-induction of metabolism and establishment of steady state plasma concentrations.<sup>49</sup> However, a case:control study examining development of CNS side effects in patients initiating efavirenz-containing HAART showed that efavirenz plasma concentrations were not significantly different in those developing CNS side effects versus those who did not.

However, specific polymorphisms in the *CYP2B6* gene affect efavirenz metabolism as this is the primary metabolism pathway for efavirenz. The *CYP2B6* gene is highly polymorphic and single nucleotide polymorphisms resulting in varying genotypes have been shown to result in elevations in peak plasma concentrations and are associated with increased CNS side effects. Several polymorphisms have been implicated, including G516T and G83T polymorphisms. Polymorphisms at the G516T position gives rise to GG wild-type genotype, GT heterozygous, and TT homozygous genotypes, homozygosity for TT, found only in African-American patients in one study, resulted in significantly increased AUC and plasma concentrations of efavirenz in excess of 6000 ng/ml. Dose reduction from 600 mg daily to 400 mg daily in patients carrying these polymorphisms may reduce CNS side effects while maintaining sufficient target  $C_{min}$  concentrations.<sup>49–51</sup>

Although the efficacy of such an approach in patients with CNS side effects without these polymorphisms has not been formally investigated, during the drug development of efavirenz there was no difference in efficacy between different doses evaluated at phase II, which included a dose of 400 mg daily, but the higher dose of 600 mg daily was chosen for investigation in phase III clinical trials. The main phase II trial of efavirenz, DMP-005, showed similar efficacy of 400 mg once daily compared to 600 mg once daily and was shown to have less CNS side effects. In addition to the potential for less side effects, dose reduction would lead to an approximately 30% reduction in the cost of efavirenz. The ENCORE 1 trial aims to compare the efficacy and safety of first-line treatment with efavirenz at the standard 600 mg once-daily dose versus the 400 mg once-daily dose in 600 patients.<sup>52</sup>

## Nevirapine

Nevirapine is a dipyrindodiazepinone, structurally related to the benzodiazepines. Its bioavailability is independent of

food intake and its long half-life supports once-daily dosing. Like efavirenz, nevirapine is metabolized by and induces the CYP450 enzyme system, predominantly through CYP3A4 with some involvement of CYP2B6. It also induces its own metabolism within the first 2 weeks of therapy and is initially used at a reduced dose of 200 mg daily, raising to 400 mg daily after 2 weeks of therapy.<sup>16</sup>

Toxicity associated with nevirapine focuses on hypersensitivity reaction and hepatotoxicity. These reactions are most likely to occur within the first 8 weeks of treatment, with hepatotoxicity in particular observed in patients initiating nevirapine-containing HAART at higher CD4<sup>+</sup> T-cell counts. As a result, nevirapine should be avoided in antiretroviral naive patients with CD4<sup>+</sup> T-cell count is >250 cells/ $\mu$ L in women and >400 cells/ $\mu$ L in men. Rash is common, occurring in approximately 10% patients and should be closely monitored as it may accompany a more severe hypersensitivity reaction, in which case the drug should be discontinued.<sup>16,53</sup>

## Etravirine

Etravirine was approved for use by the FDA in January 2008 for treatment-experienced HIV-infected patients. As food increases etravirine absorption and bioavailability, it is recommended to dose with or after a meal. It is available in an oral formulation at 200 mg twice daily. Like efavirenz and nevirapine, etravirine undergoes CYP450 metabolism, but to a lesser extent with >80% eliminated unchanged in the feces. As a result it causes less drug interactions than other NNRTIs.<sup>45</sup>

As a second generation NNRTI, etravirine is considered to have a higher genetic barrier to resistance as it is less susceptible to high-level phenotypic resistance with single mutations.<sup>54,55</sup> As different NNRTI resistance mutations will have varying effects on the efficacy of etravirine, several resistance mutation weighting scores have been developed that predict the efficacy of etravirine as a function of the number and position of resistance mutations found. Although the highest weighted resistance mutations include Y181I and Y181V, the commonest NNRTI mutation, K103N, does not feature in the weighting and is thought to have minimal impact on the efficacy of etravirine.<sup>56</sup> However, as etravirine has a prolonged  $t_{1/2}$ , there is still increased risk of development of virological failure with resistance during periods of nonadherence (see section on pharmacodynamics above).

Etravirine significantly interacts with other antiretrovirals. It decreases the  $C_{min}$  of the protease inhibitor atazanavir by up to 37% even in the presence of ritonavir boosting and decreases exposure to the CCR5 antagonist maraviroc by 53%, necessitating dose adjustment of maraviroc to 600 mg BID in the absence of concomitant administration of ritonavir within the regimen. In contrast, etravirine increases concentrations of the protease inhibitor fosamprenavir. Careful consideration of these complex interactions is required when constructing HAART regimens containing these agents.<sup>45,55</sup>

## IMPORTANT DRUG–DRUG INTERACTIONS WITH NNRTIs

### Methadone

Methadone replacement therapy, used in harm reduction initiatives in those with opiate addiction, has significant interactions with NNRTIs. Methadone metabolism is increased when coadministered with efavirenz or nevirapine with studies showing decreases in AUC of 52% and 46% for the S-enantiomer and R-enantiomer of methadone, respectively. Clinically, this can precipitate symptoms of methadone withdrawal. Although this can be managed with close monitoring and increasing the methadone dose, there is the added danger of methadone toxicity, which can be life-threatening, if the patient undergoes periods of unscheduled treatment interruptions or nonadherence, both of which are common in HIV-infected injecting drug users. Plasma concentrations of buprenorphine, an alternative opiate substitute, are also reduced by both efavirenz and nevirapine. In contrast, etravirine does not appear to have any clinically significant impact on methadone concentrations.<sup>57,58</sup>

### Rifampicin

The antimycobacterial drug rifampicin is a potent inducer of the CYP450 enzyme system and can decrease the AUC of efavirenz by approximately 20%.<sup>59</sup> Efavirenz is still recommended as a component of HAART in patients coinfecting with HIV and tuberculosis, with some guidelines recommending an increase in the dose of efavirenz from 600 mg daily to 800 mg daily in patients weighing over 60 kg when coadministered with rifampicin. In contrast, coadministration of nevirapine with rifampicin results in increased rates of virological failures, likely related to decreases in plasma concentrations of nevirapine and therefore the two drugs should not be used in combination.<sup>44</sup>

## PROTEASE INHIBITORS

Protease inhibitors represent a potent class of antiretroviral agents that are attractive due to their relatively high genetic barrier to resistance coupled with virological efficacy that in some cases is comparable to the NNRTI efavirenz.<sup>60</sup> Protease inhibitors are mostly lipophilic organic bases and are generally highly protein bound (Table 68.3 and Table 68.7). As most are metabolized through the CYP450 pathway, there is significant potential for drug–drug interactions.<sup>61</sup>

### Ritonavir

Although ritonavir has antiviral efficacy, it is now overwhelmingly used in clinical practice as a pharmacological booster of other drugs, principally other protease inhibitors. Its use as a PI in its own right was limited by intolerance, largely GI side effects and extreme dyslipidemia, and large pill burden. It is available in capsule (100 mg), tablet (100 mg), and liquid formulation (600 mg/7.5 mL). Ritonavir capsules require refrigeration; however,

**Table 68.7:** Pharmacokinetic, Pharmacodynamic, and Treatment Characteristics of PIs

Drug (ritonavir boosted)	Plasma $t_{1/2}$	Oral bioavailability	Dose	CSF/Plasma ratio
Atazanavir	8.6	68%(2)	300 mg/day*	0.002–0.023
Darunavir	15	82%	600 mg BID or 800 mg/day	
Lopinavir	5–6	N/A	2 tablets BID**	Not detected
Fosamprenavir	15–23	N/A		Negligible
Tirpanavir	5.5	N/A	500 mg BID	N/A
Saquinavir	7–12	4% extensive 1st pass metabolism	1000 mg BID	Negligible
Indinavir	2	62%	800 mg BID	

\*Can be dosed at 400 mg/day in the absence of ritonavir boosting.

\*\* Coformulated with ritonavir.

BID, twice daily dosing; N/A, data not available;  $t_{1/2}$ , elimination half-life; CSF, cerebrospinal fluid.

the melt extrusion tablet formulation, introduced in 2010, does not require refrigeration. Overall bioavailability of ritonavir is 60–80% and is almost entirely protein bound at 99%.<sup>17</sup>

Ritonavir is a powerful inhibitor of the CYP3A4 isozyme and it is this property which is exploited in order to pharmacologically enhance exposure of other antiretrovirals metabolized by CYP3A4, specifically other protease inhibitors, resulting in decreased dosing requirements and longer dosing intervals. However, potent inhibition of the CYP3A4 gives rise to multiple drug–drug interactions. Ritonavir inhibits other drug transport proteins and efflux pumps including the multi-drug resistance transporters MDR1 (also known as P-glycoprotein) and MDR2 of which other PI as well as many other drugs are substrates.<sup>62,63</sup>

Common drugs that interact with PI include HMG-Co A reductase inhibitors (commonly known as statins) fluticasone, an inhaled corticosteroid, and phosphodiesterase inhibitors used in erectile dysfunction.<sup>48</sup> Systemic exposure of statins, especially simvastatin, which is metabolized by CYP3A4, is greatly increased in the presence of ritonavir, increasing the potential for statin-induced hepatotoxicity or myositis. Concomitant use of ritonavir with fluticasone nasal spray results in 350-fold increase in the AUC and 25-fold increase in the  $C_{max}$  of fluticasone, which can lead to steroid toxicity and Cushing syndrome in some patients. Additionally, discontinuation of ritonavir in this setting can result in severe Addisonian symptoms due to relative steroid withdrawal. Coadministration of ritonavir results in an 11-fold and 49-fold increase in exposure to the phosphodiesterase inhibitors sildenafil and vardenafil respectively and a fourfold increase in the AUC of rifabutin, an antimycobacterial drug.<sup>17,61</sup>

## Atazanavir

Atazanavir has an elimination half-life that favors once-daily dosing and is usually dosed at 300 mg daily with 100 mg ritonavir, although it can also be used “unboosted” at a daily dose of 400 mg. It is metabolized via CYP3A4 and is also a potent inducer of P-gp in the enteric lumen. It is predominantly eliminated via the liver with very low renal clearance.<sup>64</sup>

Atazanavir inhibits UDP-glucuronyl transferase, resulting in elevations in circulating concentrations of unconjugated bilirubin in most patients, with scleral icterus occurring in a minority, necessitating treatment discontinuation in approximately 4% of patients. Elevations in bilirubin are not considered to be hepatotoxic and most treatment discontinuations arise due to cosmetic implications arising from icterus.<sup>65</sup>

The bioavailability of atazanavir is approximately 62% and is optimal at a lower gastric pH. Concomitant use of proton pump inhibitors (PPI) reduces the overall bioavailability of the drug and therefore concomitant use of atazanavir and PPI is contraindicated.<sup>14</sup> Although H<sub>2</sub> receptor antagonists can be used as an alternative to PPIs, these should be administered at least 10 hours after atazanavir is dosed. As described above, use of atazanavir in combination with the NNRTI etravirine is not recommended as atazanavir exposure is significantly reduced. Conversely coadministration of atazanavir and nevirapine results in increased nevirapine exposure and increased risk of toxicity.<sup>64,66</sup>

CSF penetration is poor, with one study suggesting median CSF concentrations with or without ritonavir of 10.3 (<5–21.1) ng/mL and 7.9 (6.6–22) ng/mL with one in four CSF samples having concentrations <5 ng/mL, below the estimated  $IC_{50}$  for atazanavir (approximately 1–11 ng/mL).<sup>66,67</sup>

## Darunavir

Darunavir is approved for use in both antiretroviral naive and treatment-experienced patients. It is dosed at 600 mg twice daily with 100 mg ritonavir and administered with food. It can also be dosed at 800 mg daily with 100 mg ritonavir in antiretroviral-naive patients. Darunavir absorption is dependent on P-gp protein transportation across the intestinal lumen and it is highly protein bound (approximately 95%). It undergoes hepatic metabolism through CYP3A4 and is a weak inducer of CYP2C9 with approximately 7% of the drug eliminated through the kidney.

As darunavir contains a sulfonamide moiety, it can cause allergy and rash in patients with a known sulfonamide allergy. Darunavir can be administered with etravirine despite decreases in etravirine AUC (37%) and  $C_{min}$  (49%), due to demonstrated clinical efficacy and safety of this combination in phase III clinical trials.<sup>68,69</sup>

## Lopinavir/Ritonavir

The lopinavir/ritonavir coformulated protease inhibitor (LPV/r) became available in 2000. It is the only PI in which ritonavir is

coformulated with another protease inhibitor within the same tablet. The adult tablet formulation contains lopinavir 200 mg and ritonavir 50 mg per tablet and can be dosed with or without food. The usual dose is two tablets twice a day. A liquid formulation of LPV/r (400 mg lopinavir/100 mg ritonavir per 5 ml) is also available, the usual dose being 5 ml twice daily with food. In addition to twice-daily dosing, once-daily dosing of LPV/r (four tablets) is an additional option in antiretroviral-naïve patients, although one study suggests that twice daily is still preferred in patients with high baseline HIV RNA >100,000 copies/ml. Once-daily lopinavir/ritonavir is not recommended in treatment-experienced patients and pregnant women.<sup>48,70</sup>

Lopinavir undergoes almost exclusive hepatic metabolism via CYP3A4 with renal elimination accounting for less than 3%. Moderate hepatic impairment (Child-Pugh B) increases lopinavir exposure by up to 30%.

Common side effects of LPV/r include gastrointestinal upset, diarrhoea, and dyslipidemia. With previous capsule formulations of LPV/r, diarrhea was more severe when dosed once daily. Although one small study suggested higher rates of diarrhoea with once-daily tablet dosing, a larger trial of 664 patients demonstrated similar rates of gastrointestinal side effects and virological suppression with once-daily and twice-daily dosing regimens.<sup>3</sup> Antiretroviral dyslipidemia will be discussed later in this chapter.

## Fosamprenavir

Fosamprenavir, a pro-drug of amprenavir, has a more favorable pharmacokinetic profile than amprenavir, allowing decreased pill burden and potential for twice-daily or once-daily dosing. It can be dosed in several regimens comprising either 1400 mg daily or 700 mg twice daily when boosted with ritonavir or 1400 mg twice daily when administered without ritonavir.

Fosamprenavir is hydrolyzed to active amprenavir by hydrolysis within gut epithelium. It is largely protein bound and undergoes hepatic metabolism via CYP3A4 with minimal renal elimination. As exposure to amprenavir increases considerably with hepatic impairment, dose reduction is recommended in those with hepatic dysfunction. Toxicities include rash (fosamprenavir contains a sulfonamide moiety), hepatitis and diarrhoea.<sup>34</sup>

## Other Protease Inhibitors

Although indinavir was one of the first PI approved for use, it is now no longer preferred in first-line HAART because of tolerability issues and heavy pill burden. Like other PIs, it is metabolized via the CYP3A4 system and is dosed at 800 mg twice daily with ritonavir boosting. Principal toxicities include renal dysfunction secondary to crystallopathy, presenting as crystaluria, nephrolithiasis, and renal angle pain with symptoms seen in up to 42% of treated patients. Hydration of 150 ml/hr throughout the day is recommended to avoid formation of renal crystals.<sup>71</sup>

Similarly, nelfinavir is another PI that is no longer recommended in first-line management of HIV infection largely due to a lack of

potency when compared to other antiretrovirals and intolerance principally diarrhoea.

## ENTRY INHIBITORS

### Maraviroc

Entry of HIV virus into cells requires interaction between the virus and cellular chemokine co-receptors, either CXCR4 or CCR5. Circulating viruses can be termed CCR5 tropic, CXCR4 tropic or mixed tropic depending on the predominant co-receptor used by circulating virus or sequences of the V3 loop of gp120. Maraviroc is an allosteric reversible inhibitor of the CCR5 co-receptor, approved for use in both treatment-experienced and treatment-naïve patients who are infected with CCR5-tropic HIV virus.<sup>48,72</sup> It binds to the transmembrane co-receptor cavity, which prevents interaction of the V3 loop of viral gp120 with the CCR5 co-receptor, thus preventing viral entry.<sup>73</sup> Additional antiviral effects include the inhibition of syncytia formation (fusion between infected and uninfected CD4<sup>+</sup> T-cells) and blockade of gp120-induced apoptosis.<sup>7,74</sup>

Maraviroc is available in 150 mg and 300 mg tablet with variable dosing (see below) has an oral bioavailability of approximately 33% and is 76% protein bound. It is metabolized by CYP3A4 with P-gp transportation in addition to significant renal elimination, accounting for almost 25% of total drug elimination, although in the presence of strong CYP inhibition this may be greater.

Maraviroc is a substrate for P-gp and CYP3A4 and is therefore subject to significant drug–drug interactions. As the AUC of maraviroc is related to antiretroviral efficacy, dosing of maraviroc varies considerably depending on which other drugs are used in the HAART combination (Table 68.8).<sup>75</sup>

Use of maraviroc is complicated by the requirement to identify circulating virus as being CCR5-tropic. Various tests have been introduced to help determine viral tropism, including cell-based infectivity assays and genotypic assays that sequence the V3 loop of the viral envelope glycoprotein gp120.<sup>76</sup> Virologic failure of maraviroc-containing HAART may be related to emergence of CXCR4 tropic virus or may result from development of resistant mutations within CCR5-tropic virus. Genotypic resistance to maraviroc arises due to mutations in the V3 loop.<sup>7,77</sup> Several distinct resistance mutations within the V3 loop region have been described in maraviroc treatment failures.<sup>7,74</sup>

### Enfuvirtide

Enfuvirtide (T20) is the only licensed fusion inhibitor class of antiretroviral agents. Fusion inhibitors prevent the final step of HIV entry into target cells. Binding of virus to the CD4 receptor and chemokine co-receptor induces conformational changes in the viral gp41 envelope protein, leading to translocation of the N-terminal fusion peptide of gp41 into the target cell membrane while the transmembrane anchor remains in the viral membrane. This “pre-hairpin intermediate” structure of gp41 is the target of enfuvirtide.<sup>78</sup>

**Table 68.8:** Maraviroc Dosing Recommendations: Dosing Schedules Dependent on Coadministered Antiretroviral Regimes and Medications

	Recommended maraviroc dose		
	150 mg Twice daily*	300 mg Twice daily	600 mg Twice daily
Concomitant medication	Atazanavir ± ritonavir	NRTIs	Efavirenz
	Darunavir/ritonavir	Nevirapine (without PIs except tipranavir/ritonavir)	Etravirine
	Lopinavir/ritonavir	Tipranavir/ritonavir	Rifampicin
	Fosamprenavir ± ritonavir	Enfuvirtide	
	Saquinavir/ritonavir	Raltegravir	
	Indinavir		
	Nelfinavir		
	Efavirenz + lopinavir/ritonavir		
	Efavirenz + saquinavir/ritonavir		
	Nevirapine + PI (except tipranavir/ritonavir)		

Enfuvirtide is a relatively large peptide comprised of 36 amino acids, necessitating administration by subcutaneous injection dosed at 90 mg twice daily. As it is administered subcutaneously, it has high bioavailability (>80%) and is 92% protein bound. It has poor CNS penetration, having a very low CSF:plasma ratio.<sup>79</sup> Its efficacy in heavily treatment-experienced patients was demonstrated in a number of studies, including the TORO-1 (USA) and TORO-2 (Europe and Australia)<sup>80</sup> trials and in the RESIST, MOTIVATE, BENCHMRK and POWER trials when used in combination with tipranavir, maraviroc, raltegravir, and darunavir, respectively.<sup>72,81–83</sup>

Enfuvirtide pharmacokinetics demonstrate large inter-patient variability, with low-plasma drug concentrations observed in some patients. Resistance can rapidly develop to enfuvirtide and, although resistant virus demonstrates reduced viral replicative capacity, there is no clinical benefit from continuing enfuvirtide in the setting of virological failure.

The major treatment-limiting side effect is injection site reactions which occur to a mild extent in the majority of patients but can be serious and treatment limiting in some cases.<sup>79,84</sup>

## INTEGRASE INHIBITORS

### Raltegravir

HIV integrase mediates incorporation of viral DNA into the host cell genome. Raltegravir is currently the only integrase strand transfer inhibitor licensed for use with efficacy demonstrated in the BENCHMRK (antiretroviral-experienced patients) and STARTMRK (antiretroviral naive patients) clinical trials.<sup>82,85</sup> Raltegravir is available in tablet formulation (400 mg), dosed at 400 mg twice daily. It is 83% protein bound with CSF:plasma ratios ranging from 0.01 to 0.61 (median 0.03) in one study. Raltegravir is metabolized via UGT1A1-mediated glucuronidation with no involvement of the CYP450 system, therefore reducing drug–drug interactions. However, strong inducers of UGT1A1 may affect raltegravir concentrations.<sup>86</sup>

Notably, raltegravir pharmacokinetic and pharmacodynamic studies have revealed no apparent relationship between either minimum or average raltegravir plasma concentrations and virological suppression. *In vitro*, inhibition of viral replication in infected cells exposed to raltegravir persists after removal of extracellular raltegravir, suggesting a persistent intracellular inhibition of HIV integrase, which some have referred to as a “post-antibiotic” effect. This may arise as a result of intracellular accumulation of raltegravir (similar to that observed with NRTI) and therefore a prolonged intracellular  $t_{1/2}$ .<sup>87</sup>

Like enfuvirtide, use of raltegravir in HAART combination that does not include other active agents results in a rapid loss of antiviral activity.<sup>88</sup> Raltegravir has a relatively low genetic barrier to resistance and, coupled with its prolonged  $t_{1/2}$ , results in increased virological resistance with treatment failure. In addition, there is evidence of substantial cross-resistance between raltegravir and other integrase inhibitors in development, such as elvitegravir (discussed below). The development of the Q148H and N155H point mutations in HIV integrase correlates with decreased efficacy of raltegravir, but with significantly reduced viral replicative capacity, with some arguing for continuation of raltegravir in an intensified antiretroviral regimen in heavily pre-treated patients with triple-class resistance.<sup>10,89</sup>

## ANTIRETROVIRAL DRUGS IN DEVELOPMENT

Several agents are in the latter stages of development and may add considerably to the antiretroviral armamentarium, promising to combine efficacy with the potential for new fixed-dose combinations to help improve adherence to treatment.

### Cobicistat

Cobicistat is a selective inhibitor of CYP3A4 that, unlike ritonavir, lacks antiretroviral activity. It may help replace ritonavir as the predominant pharmacological enhancer of other antiretroviral

drugs, namely, protease inhibitors and the second-generation integrase inhibitor elvitegravir (see below). Lack of antiretroviral activity and decreased propensity to cause dyslipidemia confers advantages of use of cobicistat over ritonavir, especially in HAART regimens that do not contain protease inhibitors. As it is highly water soluble, it can be coformulated with other antiretrovirals into fixed-dose combinations (FDC). Studies have shown that combinations containing cobicistat with atazanavir and the fixed-dose combination of TDF and FTC (Truvada®) compared with ritonavir-boosted atazanavir with Truvada have comparable virological efficacy and similar CD4+ T-cell responses. Early studies have, however, shown an increase in serum creatinine in patients receiving cobicistat, felt to be secondary to inhibition of tubular secretion of creatinine rather than an abnormality of glomerular filtration, as measured creatinine clearance was unchanged in those experiencing creatinine rises.<sup>90–92</sup>

### Elvitegravir

Elvitegravir is a second-generation integrase inhibitor, based on a modified quinolone antibiotic structure, with potent activity against HIV-1. HIV integrase has a single-binding site for magnesium, an ion required for strand transfer reactions and the assembly of integrase onto specific viral donor DNA fragments. By binding these magnesium cations, elvitegravir selectively inhibits the strand transfer reaction. Elvitegravir retains antiretroviral activity against multiple-drug-resistant HIV-1 *in vitro*. It is predominantly metabolized via CYP3A4 with minor metabolism occurring via glucuronidation using the UGT1A1 and UGT1A2 pathways. As such it is susceptible to boosting with both ritonavir and cobicistat, with pharmacokinetics supporting once-daily dosing. Maintenance of effective  $C_{min}$  concentrations is required for antiviral activity with a dose of 150 mg daily combined with ritonavir being explored in phase II and III clinical trials.<sup>10,93</sup>

Elvitegravir has been combined with cobicistat, tenofovir, and emtricitabine to produce a four-drug FDC—the “Quad” pill. In recent data, the quad pill demonstrated similar virological efficacy when compared to the three-drug FDC-containing tenofovir, emtricitabine and efavirenz (Atripla®), with fewer adverse events seen with the use of the quad pill, specifically efavirenz-associated CNS side effects.<sup>90</sup>

### Rilpivirine

Rilpivirine is an investigational, second-line NNRTI currently being studied in phase III clinical trials. It has strong binding properties and conformational flexibility that allows the drug to overcome mutations usually conferring NNRTI resistance such as the K103N mutation. However, it shares phenotypic cross-resistance with etravirine-associated resistance mutations. Rilpivirine pharmacokinetics differ significantly to etravirine in that its long elimination half-life of 38 hours favors once-daily dosing and potential coformulation into once-daily fixed-dose combinations. Its oral bioavailability is significantly increased with food and it is over 99% protein bound.

Rilpivirine is a substrate of CYP3A4 enzyme activity and is slowly metabolized in human hepatocytes through glutathione-dependent conjugative metabolism.<sup>94,95</sup>

The two phase III clinical trials, ECHO and THRIVE, compared rilpivirine with efavirenz when used with a NRTI backbone. Although 48-week data from both studies suggested non-inferior virological efficacy with rilpivirine-containing HAART, further analyses revealed more treatment failures related to tolerability in those on efavirenz-containing regimens (6.7% vs. 4.8% for efavirenz and rilpivirine-containing regimens respectively in pooled results) and more treatment failures related to virologic failure with rilpivirine-containing regimens (pooled results showing 9.0% vs. 4.8% virological failures in rilpivirine versus efavirenz-containing regimens, respectively).<sup>96</sup>

## Antiretroviral Toxicities

### MITOCHONDRIAL TOXICITY

All NRTIs inhibit cellular DNA polymerases of which HIV reverse transcriptase is one. NRTIs can also bind to other human DNA-polymerases, such as DNA polymerase-beta (necessary for repair of nuclear DNA) and mitochondrial DNA polymerase-gamma, which is exclusively responsible for the replication of mitochondrial DNA (mtDNA).

Mitochondrial DNA encodes for several polypeptides important in metabolic processes such as oxidative phosphorylation and the mitochondrial electron transport chain, which produces energy in the form of ATP. If NRTIs accumulate within the cells and are phosphorylated to their active forms, they are capable of disrupting mitochondrial function, leading to accumulation of reactive oxygen species, decreased tissue oxidative respiration, and increases in anaerobic respiration, resulting in increased production of lactic acid as a by-product.<sup>41,97</sup>

The range of toxicities resulting from NRTI-induced mitochondrial dysfunction tends to mirror the clinical features observed in inherited mitochondrial diseases and includes hepatic steatosis, lactic acidosis, myopathy, peripheral neuropathy, pancreatitis, and loss of peripheral adipose tissue (lipoatrophy). Each of these toxicities may occur in isolation or in various combinations, reflecting tissue-specific effects of NRTIs. This likely relates to the different affinities of specific NRTI for cellular kinases, which phosphorylate the NRTIs to their active forms. The activity of these cellular kinases differs significantly between tissues, resulting in accumulation of different NRTIs within specific tissues depending on specific cellular kinase activity within that tissue and the affinity of the drug for the specific kinase.<sup>48,98</sup>

Although inhibition of DNA Pol-gamma by NRTI, leading to mitochondrial DNA depletion and dysfunction, has been proposed to underlie many of these toxicities, mitochondrial dysfunction with exposure to NRTI has been observed both *in vitro* and *in vivo* in the absence of depletion of mitochondrial DNA, suggesting mechanisms other than inhibition of DNA pol-gamma through which NRTIs can cause mitochondrial dysfunction.<sup>97,99</sup>

## LACTIC ACIDOSIS AND HYPERLACTATEMIA

Lactic acidosis is a severe, life-threatening systemic form of mitochondrial dysfunction, seen mostly with the use of stavudine and didanosine but with cases described with use of most NRTIs.<sup>48</sup> It is a relatively rare presentation; in one randomized study of patients receiving combination NRTI backbone comprising ddI and d4T, the incidence of lactic acidosis was 3.2/1000 persons years of therapy. Most cases occur within the first 12 months after treatment initiation and women and those with higher body mass index are at higher risk of developing the condition.

Affected patients can present with rapid weight loss, nausea, tachypnea, malaise and abdominal pain with investigations revealing a metabolic acidosis, often with hepatic dysfunction. Management comprises discontinuation of antiretrovirals with supportive management of acidosis and end-organ dysfunction. Routine serum lactate measurement or measurement of mtDNA levels in peripheral blood have both been shown not to be predictive of the development of subsequent lactic acidosis and the mainstay of monitoring remains clinical vigilance to enable rapid identification of the onset of the condition.<sup>41</sup>

## LIPOATROPHY

Loss of subcutaneous adipose tissue is recognized as one of the major long-term side effects of antiretroviral therapy.<sup>100</sup> This largely irreversible process begins approximately 6 months after treatment initiation and those affected experience a selective, progressive loss of subcutaneous adipose tissue (with maintenance of muscle mass and stable or increasing visceral adiposity) as long as the causative antiretroviral agents are continued. Development of this clinical syndrome is associated with a dyslipidemia characterized by high total and LDL cholesterol, low HDL cholesterol and hypertriglyceridemia, and increased insulin resistance and a propensity to develop type 2 diabetes mellitus. These metabolic derangements may increase the risk of subsequent cardiovascular disease. The syndrome has been observed most with use of the thymidine analog NRTI zidovudine and stavudine and likely arises as a result of adipose tissue-specific mitochondrial dysfunction. The only partially effective management is discontinuation or substitution of thymidine analog NRTI.<sup>79,101</sup>

## LOW BONE MINERAL DENSITY

Initiation of antiretroviral therapy has been associated with decreases in bone mineral density (BMD), with greater decreases observed in those initiating regimens containing NRTI, especially TDF, and those initiating PI. The underlying pathogenesis is unclear but involves increases in bone turnover which seem to be self-limiting in the majority of patients, with BMD stabilizing in most patients 12 months after treatment initiation. Given the high prevalence of low BMD in HIV-infected patients, routine DXA imaging is recommended for post-menopausal patients,

patients over 50 year old, those with significant steroid exposure, a family history of hip fracture, and those with a history of fragility fracture, regardless of age or menopausal status.<sup>48,102</sup>

Although animal studies of TDF in monkeys using exposures of 6–12 times normal adult AUC values resulted in significant bone toxicity in 25% offsprings, there were no significant structural abnormalities. The effect of maternal or fetal exposure to TDF on bone turnover in infants of HIV-infected mothers is yet to be established.<sup>36,103</sup>

## ABACAVIR HYPERSENSITIVITY REACTION

Treatment with abacavir has been linked to a severe hypersensitivity reaction (HSR) characterized by fever, rash, myalgias, abdominal complaints, and hepatitis. In rare cases, usually upon re-exposure to abacavir, patients may experience life-threatening fulminant reactions, including development of Stevens-Johnson syndrome and fulminant hepatitis.<sup>35</sup> Most cases present within the first 6 weeks after initiation of abacavir, although confirmed cases have been described after significantly longer exposure. The risk of developing abacavir HSR is increased in those carrying the HLA B\*5701 allele, with the risk of development of abacavir HSR largely avoided by avoiding administration of abacavir to HLA B\*5701 positive patients. In the absence of HLA screening, where cases of abacavir HSR are suspected, abacavir should be permanently discontinued.<sup>104,105</sup>

## DYSLIPIDEMIA

Drugs within all three major antiretroviral drug classes, namely, NRTIs, NNRTIs and PIs, have the potential to induce dyslipidemia. The pattern of dyslipidemia differs between classes. Protease inhibitors induce a dyslipidemia characterized by high total and LDL cholesterol, decreased HDL cholesterol and elevations in triglycerides.<sup>106</sup> The extent of dyslipidemia varies significantly within the class, with more dyslipidemia observed with LPV/r than with newer boosted PIs such as atazanavir and darunavir.<sup>107,108</sup> The hypertriglyceridemia, particularly when combined with changes in adipose tissue distribution arising from lipoatrophy, is associated with increased insulin resistance and diabetes.<sup>109</sup> Dyslipidemia is at least partially reversible upon switching away from PIs while use of lipid lowering agents has limited benefit in the setting of ongoing PI exposure.

Efavirenz has been associated with elevations in total, LDL and HDL cholesterol, with nevirapine also associated with elevations in HDL cholesterol.<sup>110,111</sup> The resulting effect on cardiovascular risk is uncertain as the total:HDL cholesterol ratio remains relatively constant.

Within the NRTI class, elevations in LDL cholesterol have been demonstrated with use of stavudine, zidovudine, and abacavir, with additional increased insulin resistance also observed in patients on stavudine.<sup>112</sup> The extent of the elevations observed with NRTI use is generally smaller than those observed with PI or efavirenz.

## CARDIOVASCULAR DISEASE AND MYOCARDIAL INFARCTION

Increased rates of myocardial infarction (MI) have been observed in populations of HIV-infected patients and dyslipidemia induced by antiretroviral exposure is thought to play a role. In the Data Collection on Adverse Events of Anti-HIV Drugs (D:A:D) study, a large prospective cohort study of >30,000 HIV-infected patients with cumulative exposure to certain protease inhibitors, including indinavir and LPV/r, the risk persisted after correction for dyslipidemia, suggesting an additional yet unexplained increased risk of MI with exposure to these drugs that is not explained by the dyslipidemia alone induced by their exposure.<sup>113,114</sup>

Association between antiretroviral exposure and myocardial infarctions is not limited to exposure to PIs. Exposure to abacavir has also been implicated in increased myocardial infarctions, although the data are conflicting. In the D:A:D study, current or recent exposure to abacavir was associated with approximately twofold increase in myocardial infarction, independent of other risk factors for cardiovascular disease.<sup>114,115</sup> Although several other cohort studies of patients, most of whom were on antiretroviral therapy with undetectable HIV RNA, also demonstrated a similar effect, randomized studies in patients initiating treatment have not shown similar increased rates, possibly related to confounding introduced by inflammation arising from uncontrolled HIV viremia.<sup>116</sup> Both inflammation and platelet dysfunction giving rise to prothrombotic states have been postulated as underlying mechanisms, although potential confounding by preferential use of abacavir in patients with renal dysfunction and illicit drug users, both of whom could have increased cardiovascular risk irrespective of abacavir exposure, have also been proposed as possible explanations for increased rates of myocardial infarction in abacavir recipients.<sup>117</sup>

## Therapeutic Drug Monitoring (TDM)

In therapeutic drug monitoring, plasma drug concentrations are used to individualize and optimize therapy either by guiding dose adjustments or to help explain unwanted treatment outcomes (either lack of efficacy or toxicity). Characteristics of drugs that make them amenable to TDM are outlined in Table 68.9.<sup>48,118</sup>

In HIV, TDM is predominantly used to ensure that adequate circulating antiretroviral concentrations are achieved and, in limited cases of toxicity, to ensure that drug concentrations are not too high, as seen with several polymorphisms in CYP 2B6 in patients prescribed efavirenz that result in very high plasma concentrations and increased CNS side effects.<sup>119</sup>

There are several current indications for TDM of antiretrovirals:<sup>48</sup>

- To ensure adequate plasma concentrations of drugs in patients prescribed multiple medications with potential for drug–drug interactions.
- To explain lack of expected antiviral efficacy after treatment initiation, potentially important in pediatric and pregnant patients where drug metabolism may be significantly altered.

**Table 68.9:** Characteristics of Drugs that Favor the Use of Therapeutic Drug Monitoring

Characteristics	Measures
Plasma drug concentrations should correlate with outcome, either efficacy and/or toxicity	Dose/response relationship or curve Dose/toxicity relationship or curve
The drug should have a clear therapeutic index	Normal range of values identified Low (efficacy) or high (toxicity) concentration values identified
Measurement of drug concentrations within a specific dosing interval should be reproducible	Low intra-patient variability in drug concentration measurements TDM assay should have a low inter-test variability
There must be considerable inter-patient variability in drug concentrations	Some measures will fall within a low or inefficacious range, and high or toxic range
There should be a method to address abnormal results	Several available doses or formulations available to allow dose adjustment

- To optimize plasma concentrations in patients infected with viruses exhibiting multi-class genotypic resistance, where experimental antiretroviral combinations and doses may be attempted in order to achieve maximum efficacy. This seems to be useful with the PI class, where increasing accumulation of resistance mutations results in moderate fold change in IC<sub>50</sub> which may be overcome in some cases by increasing the dose of the drug. However, this approach is complicated by toxicity arising from dose escalation and the increasingly restricted formulations of PI available make it difficult to make small dose adjustments.<sup>120</sup>
- Patients with medical conditions that may significantly alter the pharmacokinetics of a particular antiretroviral, such as hepatic or renal impairment, malabsorption or accelerated metabolism.

The value of TDM in monitoring adherence is questionable, as drug efficacy differs considerably depending on the pharmacokinetics of a drug (particularly the  $t_{1/2}$ ), the lower limit of detection (LLD) of the TDM assay (some LLD are still well above the IC<sub>95</sub>, therefore a patient may have sufficient plasma drug concentrations to achieve virological suppression but may show up as “undetectable” on a TDM assay) and the pattern of adherence (intermittent missed doses versus unstructured treatment interruptions).<sup>121</sup>

A major disadvantage to the use of TDM in HIV is that, for the majority of antiretroviral drugs, the trough concentration of specific antiretrovirals does not correlate with the extent of viral suppression (HIV RNA). Many drugs (such as NRTIs) undergo intracellular activation (and plasma concentrations of NRTIs correlate poorly with intracellular concentrations) or have antiviral activity that persists even with undetectable plasma concentrations (such as raltegravir).<sup>119</sup> This is further complicated by differing responses of resistant viruses to antiretroviral drugs, which is partly controlled for by the use of algorithms such as the inhibitory quotient (IQ), previously described.<sup>122,123</sup>

The large inter-patient variability in plasma concentrations of NNRTIs and PIs would suggest a role for TDM with use of these drug classes, however, there are no clear therapeutic cut-offs, with patients experiencing virological failures and toxicities at similar plasma concentrations.<sup>124</sup> Several studies have examined the role of TDM in clinical practice with inconsistent results. In the VIRADAPT study, in pre-treated patients treated with new HAART regimens, antiretroviral plasma concentrations strongly predicted the plasma HIV RNA decline.<sup>125</sup>

The ATHENA study randomized treatment-naïve, HIV-infected patients starting HAART containing either nelfinavir or indinavir to TDM with relevant dose adjustments or standard of care without TDM. At 12 months better treatment responses were observed in the TDM arm for both indinavir and nelfinavir, reflecting less virological failures in the nelfinavir group with TDM-guided optimization of drug levels, and less treatment-limiting toxicity with indinavir. However, this study was performed with un-boosted PI with formulations available enabling small-dose adjustments to be made. It is uncertain if a similar approach would be either feasible or beneficial with the boosted PI regimens now commonly used.<sup>126</sup>

The use of therapeutic drug monitoring as part of the post-marketing surveillance for drug safety to reveal unknown pharmacokinetic problems, such as unexpected drug-drug interactions or to identify populations with unexpected high or low concentrations, has proven to be of benefit as it has helped to define special circumstances where drugs such as the CCR5 antagonist maraviroc require dose adjustments in order to maintain efficacy.

### Summary

As the armamentarium of antiretrovirals increases, so too does the complexity arising from their varied and sometimes complex drug interactions. Maintaining awareness of these interactions will help preserve antiretroviral efficacy and aid in the goal of long-term suppression of HIV replication and restoration of normal life-spans in those affected. Further research into development of effective fixed-dose combinations will help simplify treatment further and should be a long-term goal in ongoing drug development internationally.

## 69

### Introduction

The scale-up of antiretroviral therapy (ART) in low- and middle-income countries (LMIC) has been the largest public health undertaking to date. Access to treatment has improved dramatically in many high HIV burden countries. Data taken from cohorts in these countries have generally shown excellent outcomes with 2-year survival in the range of 60–90%.<sup>1,2</sup> These results are similar to those seen in high-income countries (HIC) apart from higher mortality during the first year of ART.<sup>3,4</sup>

The use of second-line regimens remains limited in LMIC.<sup>5,6</sup> This is likely to be because of a combination of under-diagnosis of treatment failure due to the limited sensitivity of current monitoring tools, limited access to second-line regimens, and a reluctance by treating clinicians to switch to second-line treatment, given the lack of access to subsequent treatment options. However, the number of people switching to second-line therapy will increase in coming years as access to virological monitoring and second-line agents increases and treated populations grow and mature. Second-line regimens remain three to twenty times more expensive than first-line regimens<sup>7</sup> and while price reductions have occurred, these have not been of the same magnitude seen with first-line agents. Increasing use of second-line regimens may therefore challenge the sustainability of ART programs and impact on programs' ability to continue to expand access to first-line therapy.

A key challenge for ART programs in LMIC is the appropriate use of efficacy monitoring technologies and ensuring appropriate use of second-line agents while containing the costs associated with monitoring. We outline here the key issues associated with the design of strategies to monitor the efficacy of ART in LMIC.

### Antiretroviral Efficacy Monitoring During First-Line Treatment in LMIC

The most sensitive test of antiretroviral efficacy is plasma HIV RNA, known as a “viral load” test. Despite the lack of randomized evidence of clinical benefit, treatment response is usually assessed

in HIC by 3–6 monthly measurement of plasma viral load. However, this test is relatively expensive and currently requires sophisticated laboratory infrastructure. Thus, this assay is not widely available in LMIC and is generally restricted to larger urban areas, particularly capital cities. In response to these financial and logistic constraints, alternative monitoring strategies are widely used. The World Health Organization (WHO) recommends that in settings where HIV viral load testing is not available, clinical and CD4+ T cell counting be used to detect treatment failure<sup>8</sup> as these measures are more feasible and more widely available.

### PERFORMANCE OF WHO CLINICAL AND CD4 CRITERIA FOR IDENTIFYING FAILURE OF FIRST-LINE ART

The most widely used non-virological surrogate markers of ART failure are those proposed by WHO. These include a single clinical criterion and three immunological criteria (Table 69.1). A number of studies have now documented consistently poor performance of these criteria for the diagnosis of treatment failure using a reference standard of HIV viral load with a range of clinically acceptable viral load thresholds (Table 69.2).<sup>9–12</sup> In particular, the sensitivity of these criteria is 20–33%, thus only approximately one in five to one in three individuals with virological failure is detected using these criteria. This leads to continuation of non-nucleoside reverse transcriptase inhibitor (NNRTI)-containing regimens in the presence of ongoing viral replication, leading to accumulation of HIV drug resistance mutations, diminished efficacy of the current regimen, reduced potential activity of future regimens, immunological progression, and increased risk of clinical progression and death.

**Table 69.1:** WHO Clinical and Immunological Criteria for the Diagnosis of Antiretroviral Therapy Failure

New or recurrent WHO Clinical Stage 4 condition
Fall of CD4 count to baseline or below 50% fall from on-treatment peak value
Persistent CD4 levels below 100 cells/ $\mu$ L <sup>3</sup>

**Table 69.2:** Performance of WHO Clinical and Immunological Criteria to Identify Treatment Failure

Report	Setting	Reference standard	Sensitivity (%)	Specificity (%)	Positive predictive value (%)	Negative predictive value (%)	Prevalence of virological failure (%)
An et al. (2007)*	Cambodia	VL >50	30	89	20	93	8
Chaiwarith et al. (2007)	Thailand	VL >50	20	86	12	91	9
Meya et al. (2007)	Uganda	VL >1000	31	87	16	94	8
Van Griensven et al. (2007)†	Rwanda	VL >40	27	82	17	89	12
Mee et al. (2008)	South Africa	VL >10,000	33	86	21	92	10

Abbreviation: VL: HIV viral load.

\*2003 WHO Criteria.

†2006 WHO Immunological Criteria.

The specificity and positive predictive value (PPV) of WHO-recommended clinical and CD4 criteria are also poor (Table 69.2). In published studies, the PPV ranges from 12% to 21% indicating that of those individuals designated under these criteria to be failing first-line ART, and therefore, potentially switched to expensive second-line regimens, only between one in five and one in eight are likely to be truly failing virologically. Thus the use of these criteria alone in determining the optimal timing of switch to second-line therapy is likely to result in significant inappropriate use of these expensive agents.

### ALTERNATIVE MONITORING CRITERIA

The relatively poor performance of WHO clinical and CD4 criteria for treatment failure has led to investigation of alternative non-virological criteria. Overall, attempts to identify alternative immunological criteria have been hampered by discordant immunological and virological responses to ART, i.e., the phenomenon where virological success is not matched with an increase in CD4 count, or vice versa. Thus where improvements in sensitivity have been identified, this has come at the cost of specificity and PPVs, with the latter generally remaining under 25%.<sup>10,11,13,14</sup> Another approach, for which some preliminary data exists, suggests possible benefit from adding simple laboratory or clinical markers such as “papular pruritic eruptions” to the existing WHO criteria,<sup>15,16</sup> but further work is required to define the potential benefit of this approach.

Investigators have also explored the potential role of adherence monitoring in the detection of treatment failure. Part of the rationale for this is that poor adherence is an “upstream” event that precedes virological failure, in contrast to detectable changes in CD4 counts, which are “downstream” effects that follow virological failure. Self-reported adherence has been the most widely used method for monitoring ART adherence and has been shown to be predictive of HIV viral rebound in some settings.<sup>17</sup> Furthermore, specific patterns of adherence, such as interruption of NNRTI-based treatment, has been shown to pose a greater risk of virological rebound than irregularly missed doses.<sup>18</sup>

An alternative to self-reported adherence is prescription- or pill-based adherence measures, referred to as pharmacy

adherence measures (PAMs). In a study conducted in southern Africa, these measures were superior to CD4 count criteria in predicting virological failure 6 and 12 months after initiating ART and adherence assessments performed prior to viral load and CD4 count assessments, were as accurate as CD4 count changes in predicting virological failure.<sup>19</sup> A study from Canada described PAMs predicting future viral rebound in an analysis of repeated measures of adherence that accounted for changes in adherence over time.<sup>20</sup> Additionally, US investigators have reported virological failure associated with poor “upstream” adherence assessments from electronic pill bottle caps (MEMS® [Aardex]). Poor adherence up to 90 days prior was associated with virological failure, suggesting there is sufficient time to implement adherence interventions that may improve virological outcomes.<sup>21</sup> Finally, a cross-sectional study in Nigeria described a combination of self-report adherence assessments and CD4 change criteria performing better than a WHO-based clinical and CD4 algorithm for detecting virological failure.<sup>22</sup>

If adherence monitoring is to be used to detect treatment failure, it is important to consider the relative qualities of alternative adherence-monitoring methods. Many methods to assess adherence, including unannounced pill counts, monitoring of ARV drug levels, electronic pill bottle caps (MEMS® [Aardex]) and web-connected pill boxes, are resource intensive and largely confined to research settings in both HICs and LMICs. Compared to self-reported adherence, which can be affected by recall or social desirability bias, PAMs are objective and may be calculated from routinely available medical and pharmacy records.<sup>23</sup> Furthermore, in studies reporting both self-report and PAMs, the pharmacy measure has been a more potent predictor of the virological outcome, whether it is virological suppression,<sup>24</sup> viral load change,<sup>25</sup> or virological failure.<sup>26–28</sup> Although PAMs have been consistently shown to predict virological failure in LMICs,<sup>26,28–30</sup> the data are limited by the variety of PAMs reported, including pill counts in clinic, “on-time” ART pick-up, and the amount of time a patient is in possession of a defined ART supply. Further studies that compare different types of PAMs, and define their relative advantages in comparison with adherence self-report, are needed to identify the best surrogate measures of virological failure.

## OUTCOMES OF NON-VIROLOGICAL MONITORING

Studies from LMIC have shown a high prevalence of resistance mutations at the time of treatment failure as defined by clinical and immunological criteria (Table 69.3).<sup>9,31</sup> In these studies the prevalence of resistance mutations would result in a very low likelihood of efficacy from first generation NNRTIs, and significantly diminished efficacy of nucleoside reverse transcriptase inhibitors (NRTIs) and second-generation NNRTIs.<sup>32</sup> Two studies have looked at the accumulation of resistance mutations in patients who were kept on a failing first-line regimen. Accumulation of resistant mutations occurred at a rate of 0.6 per 6 months to 1.6 per year of delay, and the additional mutations were mainly thymidine analogue mutations. A meta-analysis of published literature on resistance to first-line NRTI-NNRTI based highly active antiretroviral therapy compared cohorts with frequent viral load monitoring (at least 3-monthly) and no monitoring or infrequent monitoring (6 months or more). They found that patients coming from programs with no viral load monitoring have significantly more resistant mutations (NNRTI, M184V, and TAMs).<sup>33</sup> This study also suggested that at least 3-monthly viral load monitoring could reduce the accumulation of drug resistance mutations.

The clinical significance of delayed switching with non-virological monitoring remains to be clearly defined. In settings where there is an abundance of treatment options, virological failure does not always translate into a difference in clinical outcomes<sup>34</sup>; whereas, other studies have shown that delays in switching to a second-line regimen results in increased mortality when the failing regimen is a non-protease, inhibitor-based regimen.<sup>35</sup> In Côte d'Ivoire, with restricted access to second-line regimens, Seyler and colleagues showed that patients with a detectable viral load had an increased risk of immunological failure, but at 18 months there was no difference in morbidity between the patients who switched in time and those who remained on a failing regimen.<sup>36</sup> Emerging data regarding switch to second-line regimens have shown high mortality prior to switch and 10% mortality in the first year after switch,<sup>37</sup> but otherwise reassuring preliminary data with regard to the clinical and immunological efficacy of WHO-standard second-line regimens (boosted protease inhibitor-based) in programs

adopting non-virological approaches to monitoring of patients on ART is seen.<sup>37,38</sup>

## COMPARISONS OF VIROLOGICAL AND NON-VIROLOGICAL MONITORING STRATEGIES

Various approaches have been taken to investigate potential differences between virological and non-virological monitoring strategies. In a mathematic model based on outcome data from sub-Saharan African cohorts, viral-load monitoring in addition to CD4 and clinical monitoring did not have an impact on long-term survival in patients taking antiretroviral treatment.<sup>39</sup> Observational data from the ART-LINC cohort collaboration, based predominantly in sub-Saharan Africa, did not detect any increase in mortality in programs that had no viral-load monitoring; however, these data were drawn predominantly from the first year of ART during which time monitoring strategies are unlikely to have significant effect on clinical outcomes.<sup>3</sup>

Two randomized trials conducted in sub-Saharan Africa have compared alternative monitoring strategies. Unpublished adjusted analyses from the Home-Based AIDS Care study, conducted in rural Uganda, suggested that participants randomized to clinical and CD4 cell monitoring had a reduced risk of new AIDS-defining events or death when compared with clinical monitoring alone but viral load did not provide additional benefit to clinical criteria combined with CD4 counts.<sup>40</sup> However, these results should be interpreted with caution, given the study has never been published and the results of unadjusted analyses have not been made known. More recently, the results of the Development of Antiretroviral Therapy in Africa study were published.<sup>41</sup> In this large randomized trial of clinical monitoring versus clinical, CD4, and toxicity monitoring a significantly greater proportion of participants in the clinical monitoring arm suffered a WHO stage 4 event or death (event rate 6.94 vs. 5.24 per 100 person-years; Hazard Ratio 1.31 [1.14–1.51],  $P < 0.0001$ ). Neither arm included unblinded viral-load testing. A cost-effectiveness analysis based on these data suggested that CD4 cell monitoring is unlikely to be cost-effective unless used from the second year of treatment onwards and reagent costs were below US \$3.80. However, this analysis was based upon branded ART costs, and most participants were treated with a triple nucleoside regimen, limiting the generalizability of this threshold.

**Table 69.3:** Prevalence of Resistance Mutations in Patients Who Present with Immunological and Clinical Failure and Who Have a Detectable Viral Load Above 1000 copies/ml

	NNRTI (%)	M184V (%)	TAMS (%)	K65R/K70E (%)	Q151M (%)
Malawi (Hosseinipour 2009)	93	81	56	23	17
India (Kumarasamy 2009)	88	79	60	5	–

NNRTI: Non-nucleoside reverse transcriptase inhibitor.

## ALTERNATIVE APPROACHES TO THE USE OF VIRAL-LOAD TESTING

Despite the lack of clear evidence that virological monitoring is superior to non-virological monitoring, it remains evident that even with foreseeable improvements in the performance of non-virological criteria the majority of patients meeting these criteria will be false positive cases of virological failure. Given these test performance characteristics and current costs of viral-load testing and first- and second-line regimens many researchers have, therefore, recommended that where some viral testing is feasible,

confirmation of virological failure in individuals with suspected treatment failure using a viral load test should be implemented prior to switching to second-line treatment.<sup>42</sup> Indeed, a cost-effectiveness analysis has suggested viral-load testing to confirm suspected virological failure based on immunological and clinical criteria is highly cost-effective.<sup>43</sup>

Two potential forms of these “targeted” viral-load testing strategies exist. Firstly, current low-sensitivity non-virological criteria, such as those currently recommended by WHO, can be used for the initial evaluation. This strategy emphasizes the importance of reducing or eliminating false positives and inappropriate switching to second-line therapy.<sup>44,45</sup> Alternatively, a more sensitive “screening” set of non-virological criteria can be identified. This strategy effectively eliminates false positives, but also seeks to reduce false negatives. Prospective studies of this strategy are currently under way.

## Conclusion

Many barriers exist regarding optimal sequencing of HIV therapy in LMICs, including HIV efficacy monitoring. The need for HIV viral-load monitoring in LMICs remains controversial, but alternative monitoring tools based on clinical, immunological, and adherence measures have limited performance and lead to inappropriate and delayed switching. Viral load is therefore needed routinely or to confirm treatment failure before switching to second-line treatment. Nevertheless, many challenges to the widespread availability of HIV viral-load monitoring in LMICs remain, and addressing these issues will take concerted and systematic effort.

## First Decade of ARV in Africa: Overcoming Barriers to Providing ARV Therapy in Resource-Limited Settings

Nathan Ford • Alexandra Calmy

### Introduction

The international effort to scale up antiretroviral therapy (ART) in the developing world that began in 2001 has been one of the most important programs in global health.<sup>1</sup>

Initially, however, there was a considerable resistance to providing ART in developing countries. Concerns were raised that ART was too expensive, too complex, and even that Africans could not adhere to lifelong treatment because they were unable to tell the time.<sup>2</sup> In particular, concerns were raised regarding the cost-effectiveness of ART compared to prevention interventions.<sup>3</sup>

Despite these concerns, within a decade, over six million people have been successfully started on and remain on therapy. This remarkable success in expanding access to ART was achieved by a global coalition of doctors, patients, civil society actors, governments, and non-governmental organizations, who refused to accept that millions of people in the developing world would be consigned to an early death from a disease that in the West had been transformed into a chronic, manageable condition, thanks to access to effective ART available since 1996.

This chapter provides an overview of the main policy and delivery challenges to the provision of effective ART in resource-limited settings: simplifying drug regimens and treatment monitoring; reducing the cost of medicines; overcoming human resource barriers; adapting the model of delivery; and integrating new evidence to improve the package of care.

### Global Advocacy to Reduce Treatment Cost

The early reluctance to support the provision of ART in developing countries was primarily driven by the cost of treatment. The fact that antiretroviral medicines were priced beyond the reach of the majority who needed them was an issue that had been on the international agenda for several decades: at the International AIDS Conference in Stockholm in 1988, there was a debate about how to ensure people in the developing world that they could access the treatment of that time, zidovudine monotherapy, which was marketed at a price of US\$8000 per year.<sup>4</sup> Triple therapy,

made available in late 1996, which revolutionized HIV/AIDS care in the West was considered far too expensive for resource-limited settings (particularly as it must be taken for life), UN agencies,<sup>5</sup> academics,<sup>3</sup> and major donors alike<sup>6</sup> all argued against providing treatment in favor of focusing funding on prevention. As a consequence, many high-prevalence countries still had no national treatment plan. South Africa, the country with the greatest number of people living with HIV in the world (some 5.6 million people at the time), only introduced a national HIV/AIDS treatment plan in November 2003.<sup>7</sup>

Civil society groups, and in particular people living with HIV/AIDS themselves, were critical to breaking the deadlock. Patient groups in Thailand, Brazil, South Africa, India, Kenya, Uganda, and other high-burden countries formed alliances with health providers, non-governmental organizations, and health groups in developed countries to argue the case that if the cost of treatment was too high, then it must come down.<sup>8</sup> Activist demonstrations took place from New York to Delhi to raise attention about the global inequities in access to treatment.<sup>9</sup>

In South Africa, home to the largest number of people living with HIV/AIDS, the government fought (and won) a court case against a consortium of 39 pharmaceutical companies over a law that would allow the government to source more affordable sources of antiretrovirals in neighboring countries.<sup>8</sup>

In Thailand, civil society groups began to raise legal challenges to patents in order to support the local production of affordable generic versions. In 2004, the Thai courts ruled that the patent on didanosine was unlawful because it lacked sufficient inventiveness on the part of the patent holder (didanosine was invented by researchers at the US National Institutes of Health and licensed to Bristol-Myers Squibb (BMS) in 1988; BMS extended patent protection through the addition of a common antacid buffer). In the final verdict, the Thai court states that “lack of access to medicines due to high-price prejudices the human rights of patients to proper medical treatment”.<sup>10</sup> This court ruling paved the way for the generic production of a number of key antiretroviral drugs.

The Brazilian government has, like Thailand, taken a strong position against the high price of medicines resulting from

the patent protection. Both countries have established public capacity to produce medicines, and in this way have been able to produce antiretroviral drugs at a fraction of the price demanded by multinational pharmaceutical companies. These two countries have played a leadership role among developing countries by challenging the international monopolies of antiretroviral drugs.<sup>11</sup> These programs paved the way for ART scale up in their countries by demonstrating efficacy and feasibility of large-scale access to ART via the public sector.

The global effort to scale up ART was only made possible from 2001, when an Indian generics manufacturer announced that they were able to manufacture triple therapy for less than a dollar a day. Other Indian generics companies made similar announcements, establishing a dynamic of global market competition that in 10 years has reduced the price of standard triple therapy from \$US 10,000 per patient/year to around \$US60.<sup>12</sup> Indian generics companies have played a critical role in supplying affordable generic versions of antiretrovirals to developing countries, providing over half of all antiretroviral medicines used in the developing world.<sup>13</sup>

The dramatic reduction on the cost of treatment was essential to shifting the cost-effectiveness equation, and from 2003 a number of international funding streams were established to support ART scale up, notably the Global Fund for AIDS, TB and Malaria and the US President's Emergency Plan for AIDS Relief.<sup>1</sup> Such dedicated funding for HIV/AIDS has been essential to scale up efforts.

## Overcoming the Human Resource Crisis

As programs began to enroll increasing numbers of patients, so it became rapidly clear that the lack of qualified health personnel, particularly in Africa, would prove to be a major bottleneck to increasing access to treatment. As soon as access to ART began to expand, public health experts began to raise attention about the human resource crisis in Africa as one of the most important limiting factors to widespread access.<sup>14</sup>

While in Western countries, HIV/AIDS has traditionally been managed as a specialized disease requiring a range of consultants from dermatology to oncology, health centers in sub-Saharan Africa faced with a dominant proportion of the global AIDS burden have a critical shortage of the most basic essential health staff. Countries like Malawi, where adult HIV prevalence is around 10%, have almost 100 times fewer doctors per population compared to the UK.<sup>15</sup> This crisis is partly driven by proactive recruitment of health personnel by developed countries, a practice that has been framed as an international crime.<sup>16</sup>

It therefore became apparent that a simplified treatment paradigm was required in resource-limited settings, entailing a shift from a specialized medical approach to a public health approach in which the majority of clinical tasks would be undertaken by lower health cadres such as nurses.<sup>17</sup>

Given the vast number of lives being lost to HIV/AIDS every day, such task-shifting strategies had to be employed outside of a formal evidence base, rather than waiting for randomized trial data to demonstrate that nurses could perform as well as doctors in

prescribing antiretrovirals; operational research was conducted to assess the effectiveness of such a strategy at the same time as it was being rolled out as a national policy, with countries like Lesotho,<sup>18</sup> South Africa,<sup>19</sup> and Malawi<sup>17</sup> all demonstrating that with adequate training and supervision, routine clinical management of patients on ART could be delegated to nurses. The effectiveness of this approach has since been confirmed by randomized trials.<sup>20</sup>

Substantial evidence has now accumulated around the effectiveness of different modalities of task shifting in contributing to improvements in service efficiency, increased access, sustained quality of care, and improved team dynamics.<sup>21</sup>

## Simplifying Drug Regimens and Monitoring

The delivery of ART at the primary care level required a treatment that is easy to store, simple to take, and could be administered by lesser trained health cadres via standardized guidelines. The development of fixed-dose combination ART was one answer to these requirements.

WHO guidelines for antiretroviral therapy in resource-limited settings, first issued in 2001, promoted the use of non-nucleoside reverse transcriptase inhibitor (NNRTI)-based regimens as the preferred option.<sup>12</sup> This provided critical scientific and political support for the use of a simple, affordable twice-daily regimen.<sup>22</sup> Implementation at large scale began in 2003 and by 2008, access to antiretroviral drugs in low- and middle-income countries rose 10-fold.<sup>23</sup> As well as providing guidance on drug regimens, the WHO guidelines also addressed the need for simplified toxicity and efficacy monitoring: the ability to perform CD4 counts, viral load, and monitor levels of various markers of toxicity (alanine aminotransferase, lactate, and creatinine), while desirable, are not a precondition to starting treatment.

## Decentralizing HIV/AIDS Care to the Primary Care Level

Task shifting and simplification strategies have been essential to supporting equitable access to care. Doctors are in short supply and for the most part are located in hospitals in cities: rural parts of South Africa for example have 14 times fewer doctors than the national average<sup>19</sup> while over half of Mozambique's doctors are working in the capital city, Maputo.<sup>15</sup> Because of this uneven distribution of clinical staff, policies that insist on doctor-based provision of ART are, by default, policies that limit access to treatment for populations living in rural areas.

Patients who live far from healthcare services and have to travel long distances to access antiretrovirals have been found to have greater attrition and mortality rates compared to patients who leave closer to care. The cost and time required to travel to health centers have been associated with poorer adherence<sup>24</sup> and higher rates of defaulting from care.<sup>25</sup> The decentralization of antiretroviral care to health centers in rural areas is therefore essential to improving both access and equity.

Thus, another important adaptation to the standard model of HIV care practiced in the west has been the adaptation of

services such that ART could be delivered effectively at the primary care level by health center staff with supervision by clinical teams.<sup>18</sup> More recently, there has been a recognition that as the number of people on treatment continues to grow, so there will be a need to go even further in the decentralization of care and develop models of chronic disease care outside of the formal health system. In 2009, results from a cluster randomized trial done in Uganda found that home-based ART delivery was equivalent to facility-based ART delivery in terms of survival and virological suppression.<sup>26</sup> Similarly, a study in 2010 reported that in western Kenya, people living with HIV/AIDS have been trained to provide follow-up to clinically stable HIV patients in their communities and distribute ART and prophylaxis for opportunistic infections.<sup>27</sup> Such out-of-clinic approaches to ART management for stable patients will likely become increasingly important in the future as a strategy to decongest overburdened health services and simplify treatment delivery for patients.

### Improving Quality of Care

In the initial years of ART provision in Africa, HIV/AIDS was considered a humanitarian emergency, like floods and famines, and a rapid emergency response was required to reduce mortality as quickly as possible.<sup>28</sup> In order to provide effective and affordable care to the millions in need, adaptations to the western model of care were required to simplify treatment regimens and adjust delivery models to the realities of resource-limited settings.<sup>29</sup>

The need to continue to increase access to treatment for those not receiving it is still an urgent international priority. At the same time, however, there have been a number of important advances in terms of drug development and clinical science that need to be integrated into the package of care in the developing world. As developing country cohorts matured, so the limits of an emergency, public health approach for a chronic, lifelong condition became apparent.

Therefore, one of the most urgent challenges is to ensure that people are treated earlier in the course of their disease. The first step is to increase access to HIV tests and counseling; the second step is to link HIV testing with care. Finally, HIV treatment has to be started timely enough to avoid early mortality after treatment initiation.

In the earlier phases of ARV introduction in resource-limited settings, WHO recommended treating, by priority, the most severely ill patients, or patients with advanced immunosuppression (i.e.,  $<200$  CD4 cells/mm<sup>3</sup>). European and US guidelines recommended ART initiation at a CD4 cell threshold of 350 cells/mm<sup>3</sup> (moderate immunodeficiency), before severe immunosuppression occurs. This was originally based on concerns related to the accumulative risks of toxicity and drug resistance.<sup>30</sup> Such concerns have diminished in recent years as newer medicines have become available with fewer toxicities and better potency (reducing the chance of resistance development). The availability of these newer medicines, together with studies that have increased the understanding of the risks of developing life-threatening illnesses over time if ART is initiated at a low

CD4 count have shifted the risk-benefit equation.<sup>30</sup> Recent evidence from European cohorts shows that starting ART earlier (at least 350 cells/mm<sup>3</sup>) results in significant survival gains<sup>31</sup>; other cohorts analyses from the US even demonstrated a survival gain by treating even earlier, at 500 CD4 cells/mm<sup>3</sup>. The deleterious role of chronic, ongoing HIV replication is becoming clearer and thus the risk of non-HIV-related complications such as cardiovascular diseases and cancers can be reduced through earlier initiation of ART. As a result, US, French, and European guidelines have recently been revised and recognize that treatment can be initiated as early as 500 CD4 cells, especially in patients with other comorbidities, aged over 50, or with organ dysfunction.<sup>32</sup>

The need to provide ART earlier holds equally for resource-limited settings. Treatment guidelines issued by the International AIDS society in August 2008 state that “the core principle underlying these guidelines, namely pathogenesis-directed therapy with regimens designed to achieve full virologic suppression with minimal toxicity and maximal simplicity, is applicable to the developing world”<sup>33</sup> and the latest World Health Organization antiretroviral treatment guidelines for resource-limited settings released at the end of 2009 recommend a move towards earlier initiation at 350 cells/mm<sup>3</sup>.<sup>34</sup> As evidence emerges around the benefits of earlier treatment initiation in developing countries in terms of reduced mortality, morbidity, and hospitalization, so the challenge for donors and implementers will be to further adapt services in order to meet the increased demand.

Another challenge is to ensure access to some of the newer drugs with better efficacy and side-effect profiles that are brought to market. The standard treatment regimen in developing countries has relied on the drug stavudine. Reasons for choosing this drug include low cost (currently around US\$60 per person per year), availability as a fixed-dose combination that promotes adherence and simplifies drug supply management, excellent early tolerability, and its safety for use in pregnant women.<sup>12</sup> However, there are some severe side-effects associated with stavudine that have led its use to be progressively abandoned in developed countries.<sup>35</sup> In 2009, the World Health Organization revised its guidelines to recommend a move away from stavudine towards more drugs with a better safety profile, including tenofovir, which is also available as a once-daily regimen.<sup>36</sup> However, the relatively higher cost of this regimen has limited its inclusion in national protocols. Renewed advocacy efforts are needed to ensure that the price of tenofovir comes down, and that promising new drugs in the development pipeline are made accessible at an affordable price as soon as they become available.

### Looking Forward

Almost a decade ago, a common view among policy makers and donors was that ART was not an option for the developing world. At the same time as western countries were beginning to appreciate the major reductions in illness and death that ART could provide,<sup>37</sup> the provision of ART was argued to be too costly and too complex for developing countries,<sup>3</sup> and might even do harm to health services that were overburdened and under-resourced.<sup>38</sup>

Yet with three million people dying each year, mostly in Africa, withholding ART was considered simply unacceptable by a growing number of activists, academics, clinicians, and patients. Global inaction against HIV/AIDS was labeled as a crime against humanity.<sup>2</sup> A growing international movement fought against the high cost of treatment and in just a few years succeeded in reducing the price of ART to a fraction of its original price.<sup>8</sup> Small pilot programs that carefully selected a few dozen patients for treatment were rapidly swept away by demand and these pilot programs rapidly evolved into district wide programs treating thousands of people.<sup>39</sup> Treatment outcomes were evaluated and found to be as good as those reported in western settings.<sup>40</sup> The model of ART care was adapted from a resource-intensive individualized approach to a public health program that could be delivered by nurses at the clinic and community level.<sup>18</sup> Contrary to early fears, ART delivery was, after careful analysis, found to be supportive of health system strengthening.<sup>41</sup>

As coverage of ART has increased, so the broader benefits of ART are becoming apparent. In Malawi, adult mortality within the general population fell by a third as ART access increased<sup>42</sup>; similar declines in mortality have been reported elsewhere.<sup>43</sup> There is also emerging evidence to suggest that increased ART coverage may have an impact on prevention, by reducing the population-level viral load and thereby reducing the overall risk of transmission.<sup>44</sup> Mathematical models suggest that widespread ART coverage will result in a level of virological suppression at the population level that will reduce<sup>45</sup> or even eliminate<sup>46</sup> HIV transmission, and clinical trials are underway to assess the preventive impact of ART.<sup>47</sup>

Yet despite these major advances, it seems that most of the lessons of the last decade are rapidly being forgotten. In 2010, the high cost of treatment is again cited as a reason to accept sub-optimal care. The latest WHO guidelines recommend replacing older drugs long-abandoned in the west with more durable and less toxic alternatives, but because these newer drugs are more expensive, developing countries are reluctant to make the change.<sup>12</sup> Similarly, several studies have shown important benefits to starting treatment earlier, including one randomized trial which found that starting treatment earlier was associated with a four-fold decrease in mortality and a two-fold decrease in incident tuberculosis.<sup>48</sup> But lowering the threshold for initiation means that several million more people become eligible for ART, and while this may be clinically desirable, it is not politically supported at a time when many western donors are trying to get out of funding HIV/AIDS programs. As a result, just as the early benefits of ART were ignored in favor of cheaper interventions despite a clear mortality cost, this latest evidence is being swept aside by major funders who defend a policy of delaying treatment in order to ration resources.<sup>49</sup> International advisors are suggesting that treatment numbers should simply be frozen.

In 2005, the international community committed to a goal of achieving universal access to ART by 2010. Not only we have failed to achieve that goal but also the sustainability of gains made to date is under threat from multiple sides. Clinics are

reporting major stock ruptures of antiretrovirals due in part to insufficiencies in global fund financing.<sup>50</sup>

A decade ago, those in the international community who did not support the scale up of ART in Africa could argue that it was untested. In 2010, we know that treating HIV/AIDS on a large scale is entirely possible. We know that the price of treatment can be reduced; we know that simple, adapted models of delivery can support treatment provision even in highly under-resourced areas; and we know that major savings can be made by health systems that invest early. Improving the basic package of care can limit side-effects that delay the need for patients to switch to more expensive second-line regimens, while treating earlier will potentially yield massive public health benefits in terms of reduced transmission of HIV and other diseases.<sup>49</sup>

The challenge for the next decade is to increase access to treatment while at the same time ensuring that the package of care is continuously improved such that all patients—whether they happen to be born in the developed world or the developing world—can benefit from the latest improvements in drug development, clinical science, and public health.

### Summary

The last decade has seen remarkable progress in increasing access to ART in resource-limited settings. Early efforts to increase access to treatment were held back by concerns about the cost and complexity of providing ART, and fear of poor adherence leading to the development of drug resistance; however, these concerns were effectively overcome by a global coalition of health providers, activists, academics, and people living with HIV/AIDS who made the case that every effort must be made to overcome barriers to essential care when millions of lives depended on it. The high cost of treatment was reduced through advocacy efforts to promote access to generic drugs that reduced the global average cost of treatment to less than a dollar a day; the complexity of treatment was addressed through operational research to simplify treatment and monitoring protocols; the lack of human resources was overcome through task-shifting to support the provision of care by non-physicians and access was expanded through the development of models of care that could work at the primary care level. The challenge for the next decade is to increase access to treatment while at the same time ensuring that the package of care is continuously improved such that all patients can benefit from the latest improvements in drug development, clinical science, and public health.

# Antiretroviral Drugs for HIV Prevention

Hubert Maruszak • Don Smith • Brian P. Mulhall

# 71

## Introduction

Currently, no high-efficacy vaccine against HIV exists; therefore, a range of other preventive measures, behavioral and biological, are the subjects of intense scrutiny.

Among prevention options, the use of antiretroviral (ARV) therapy has attracted considerable attention. ARV therapy is the mainstay of management for patients with established HIV infection. These drugs, by blocking critical steps in viral replication, prevent immune destruction and opportunistic infections. The same medications have now been considered for additional roles in preventing the transmission of the virus to people following (predominantly) sexual exposures.

Antibiotics and antiparasitic agents have long been used as part of preventative disease control, for example, in tuberculosis and malaria. Infection with HIV poses special problems, however, and even after 25 years since the discovery of the virus we have little understanding of the initial events in its natural history.

Development and efficacy testing of large number of potential microbicides and other preventive strategies, such as ARV pre- and post-exposure prophylaxis, have been hampered by the lack of simple animal models. Until recently, the only surrogate animal models used to study intravaginal or rectal HIV transmission were macaques infected with simian immunodeficiency virus (SIV) or SIV/HIV (SHIV) chimeric viruses, an expensive option. However, in the last few years, researchers have developed “humanized bone marrow-liver-thymus” mice that are susceptible to HIV infection; these models will be referred to later.

In this chapter, we review the uses of ARV for prevention, in the approximate chronological order that they have been investigated:

- Post-exposure prophylaxis following occupational exposure to HIV (PEP)
- Post-exposure prophylaxis following nonoccupational (sexual) exposure to HIV (nPEP)
- Pre-exposure prophylaxis for women with topical microbicides containing ARV
- Pre-exposure prophylaxis of HIV with oral ARV (PrEP)

- Effective treatment of infected persons to reduce HIV transmission to their partners
- Reduction of the HIV epidemic by widespread use of effective ARV in infected individuals (Test and Treat strategy)

## HIV Post-Exposure Prophylaxis

Post-exposure prophylaxis (PEP) is the use of ARV drugs to prevent HIV infection after high-risk exposure to HIV. Despite the widespread use of PEP in developed countries, the level of medical evidence for PEP remains relatively low. This section gives a general overview of the underlying principles surrounding PEP usage; practitioners should be familiar with national and local guidelines when prescribing PEP.

The rationale for PEP comes from a combination of animal models and retrospective case-control studies in healthcare workers and studies on mother-to-child HIV transmission. In the US, a nationwide, prospective, placebo-controlled trial of prophylaxis with zidovudine (AZT) after percutaneous exposure to HIV among healthcare workers had to be discontinued when only 84 subjects had enrolled after 1 year, since thousands would be needed to assess reduction of a 0.3% risk of transmission.<sup>1</sup> Therefore, there is no randomized clinical trial evidence attesting to the effectiveness or not of PEP.

Tenofovir given within 24 hours to macaques inoculated with simian immunodeficiency virus prevented infection in all animals but the failure rate reached 50% when given later. This animal model supports recommendations that PEP should be given as soon as possible and not later than 72 hours after exposure, preferably within 24 hours.<sup>2</sup> Animal models further support a 28-day course of treatment.<sup>2-4</sup> These early animal studies were imperfect because the HIV challenge was intravenous inoculation.

Evidence that PEP can prevent transmission of HIV in humans has been limited to a single case-control study of needle-stick injury (not sexual transmission) conducted by Cardo and colleagues.<sup>5</sup> From reports to national surveillance systems in the US, Italy, France, and the United Kingdom, 33 cases of HIV acquisition from 712 needle-

stick exposures were retrospectively identified. This study showed that persons who received AZT were 81% less likely to be infected with HIV than non-treated controls (95% CI, 48–94%).<sup>5</sup> The probability of HIV infection increased when blood was visible on the device, or a needle used in an artery or vein, after deep injuries, and the use of a large bore hollow needle. An AIDS-defining illness within the source was an additional risk of infection, probably reflecting the high viral load in advanced stages of HIV infection.<sup>5</sup> On the basis of this study, the Centers for Disease Control and Prevention (CDC) published guidelines in 1998 for PEP after occupational exposure; although, recommendations for non-occupational exposure (nPEP) were not published until 2005, due to paucity of evidence. An important factor often overlooked when transposing the Cardo study to non-occupational settings was that the majority of healthcare workers received PEP *within 4 hours* of their exposure.

Evidence that the prescription of ARV drugs may prevent human-to-human HIV transmission also came from studies investigating mother-to-child transmission. A number of studies proved that AZT when given to mothers during pregnancy and newborns for six weeks after birth reduces the risk of HIV transmission by 67%. This reduction is further improved if lamivudine (3TC) is used in addition to AZT. Furthermore, even if mothers were not treated but AZT was given to newborns, the risk of HIV transmission was 9% compared with 27% when no treatment was given (see other chapters).

From these studies, there is a crude estimate of approximately 70% reduction in HIV transmission risk by using a single ARV drug, a suggestion of a further 90–95% risk reduction if two drugs are used, and an estimate of the time frame (within 24 hours but still some effect out to 72 hours) within which any protective benefit might be achieved.

Nonetheless, it should be noted that PEP failures have been reported after occupational and sexual exposure even when PEP was initiated within the recommended time frame.<sup>6,7</sup>

However, there are still a number of critical areas where evidence is lacking:

**Duration:** PEP courses shorter than 28 days have not been studied.

**Number of drugs used:** Studies to date have looked at only one or two drug therapies. There is no evidence of any additional protection by using three-drug combinations.

**Choice of drugs:** To date, only AZT, 3TC, tenofovir, and nevirapine have been studied. Nevirapine is no longer recommended because of the risk of allergic reactions and hepatotoxicity. The use of reverse transcription inhibitors has theoretical appeal as they inhibit the generation of pro-viral DNA. On the other hand, protease inhibitors, which are active only after viral integration has occurred, do not prevent cellular infection and would be considered illogical choices for PEP.

## PEP FOR OCCUPATIONAL EXPOSURE

Accidental injuries with HIV-contaminated sharps in healthcare workers pose significant risk for HIV transmission; thus all cases

should be taken seriously and treated as an emergency. Usually the HIV status of source is known thus additional information about source viral load, current ARV treatment, and history of drug resistance may assist in determining an optimal PEP regimen. While high HIV RNA plasma viral load increases risk of infection it should be noted that undetectable viral load does not eliminate risk of infection.<sup>8</sup> There are many factors which may influence HIV transmission including different phenotypes and strain virulence. Every healthcare facility should have established procedures for needle-stick injury reporting and emergency response. The PEP initiation starter packs should be available to ensure that PEP, if indicated, is commenced without delays. Baseline HIV, Hepatitis B, and C serology should be obtained and appropriate follow-up arranged at week 4–6, month 3, and month 6.

## PEP AND COMMUNITY (“STREET”) NEEDLE-STICK INJURY

There are considerable media and community fears regarding risk of HIV infection after accidental percutaneous injury with injecting equipment discarded in public places, e.g., streets, parks, beaches, or children’s playgrounds. Despite common beliefs, the risk of HIV infection from this type of exposure is very low. HIV survival in discarded needles depends on temperature, humidity, viral load, and other factors. There have been no published reports about HIV acquired through “street” needle-stick injuries. Estimation of risk of transmission is based on HIV prevalence in injecting drug users (IDUs) which varies among communities. For instance, in Australia, prevalence of HIV among IDUs is low (1% = 0.01) and PEP is not prescribed for community needle-stick injury (risk =  $1/300 \times 0.01 = 1/30,000$ ). It should be noted that Hepatitis C and B are more prevalent and easier to transmit through community needle-stick injuries than HIV. Patients should be given Hepatitis B and tetanus immunization if not immune.

## PEP FOR NON-OCCUPATIONAL EXPOSURE (NPEP)

Unprotected vaginal and/or anal intercourse is the main reason for prescribing nPEP in non-occupational settings. Contrary to occupational settings, the HIV status of the source (partner) serostatus is often unknown, nor the exact time of exposure. Therefore, in clinical practice, it is necessary to estimate the risk of HIV transmission. Various epidemiological studies give an estimate of transmission risk associated with certain activities (Table 71.1).

Where nPEP guidelines have been produced, most recommend using nPEP for high-risk exposures (usually greater than 0.0001, or 0.000067 [otherwise expressed as 1/10,000 or 1/15,000]).

To estimate the risk, the following need to be determined:

- Route of exposure (vaginal/anal/oral, insertive/receptive)
- Knowledge of risk carried by route of exposure (Table 71.1)
- Risk of a source being HIV positive (calculated as prevalence of HIV in social group to which a source belongs (e.g., het-

**Table 71.1:** Exposure and Transmission Risk Per Single Exposure

Type of exposure with known HIV+ source	Estimated risk of HIV transmission per single exposure <sup>*(9–12)</sup>
Receptive anal intercourse	1/120 (0.008)
Receptive vaginal intercourse	1/1000+ (0.001)
Insertive anal or vaginal intercourse	1/1000+ (0.001)
Receptive fellatio with/without ejaculation	Not measurable†
Insertive fellatio	Not measurable†
Cunnilingus	Not measurable†
Sharing/use contaminated injecting equipment	1/150 (0.0067)
Occupational needle-stick injury	1/333 (0.003)
Community needle-stick injury	Not measurable†
Bites, etc.	Not measurable†
Other trauma	Not measurable†
Non-occupational exposure of intact mucous membrane§ and skin	Not measurable†

\*These estimates are based on prospective studies, not cross-sectional data or figures derived from modeling.

†This estimate has been rounded down from 1/909 to 1/1000.

‡Although there have been case reports of transmission, the risk associated with the exposure is so low that it is not measurable.

§Conjunctiva, oral, or nasal mucosa.

erosexual, men who have sex with men [MSM], sex worker, or IDU). Practitioners should be familiar with local seroprevalence data. Country-specific data for general population and some sub-groups is also available through the UNAIDS/WHO Global HIV/AIDS online database at [www.who.int/globalatlas/pgrms/HIV](http://www.who.int/globalatlas/pgrms/HIV).

- The presence of genital ulcerations or other sexually transmitted diseases which increase risk of HIV transmission

*Risk of HIV Transmission = Risk carried by route of exposure × risk of source being HIV+*

**Example 1:** Heterosexual male presents for nPEP following unprotected vaginal intercourse with a female sex worker while on holiday in Bali (Indonesia)

Risk = 0.0001 (or 1/1000) (risk of the single exposure via insertive vaginal intercourse) × 0.019 (or 1/10) (10% prevalence of HIV in female sex workers in Indonesia) = 0.0000019 (or 1/10,000); whether nPEP is recommended would be equivocal in this instance.

**Example 2:** Patient is a gay male who had unprotected receptive anal intercourse with a casual male partner in Sydney, Australia

Risk = 0.008 (or 1/120) × 0.01 (or 1/10) (10% prevalence of HIV in gay males in Sydney) = 0.00008 (or 1/1200); therefore, nPEP would be unequivocally recommended.

The following general guidelines should be considered when prescribing PEP, or nPEP:

- The usual duration of treatment is 28 days
- PEP is usually indicated within 72 hours of exposure

- Commonly used two-drug regimens include
  - AZT + lamivudine (Combivir): Some patients experience gastrointestinal (GI) side effects, thus often antiemetic, e.g., metoclopramide, is added.
    - Advantages: Lower cost.
    - Disadvantages: Twice a day, GI side effects are common.
  - Tenofovir + emtricitabine (Truvada)
    - Advantages: Once a day, less side effects.
    - Disadvantages: Higher cost
- Some guidelines recommend a 3-drug regimen, when a protease inhibitor is added, e.g., lopinavir/ritonavir (Kaletra). The rationale is that a 3-drug regimen is more efficacious than a 2-drug regimen for controlling HIV replication in chronically HIV infected patients, especially when the prevalence of drug resistance in the source patient population is high.<sup>13</sup> Despite this, there is no evidence that a 3-drug regimen is superior to a 2-drug regimen
- Avoid abacavir (potential life-threatening hypersensitivity) and nevirapine (fulminant liver failure requiring liver transplant has been recorded in a US healthcare worker).<sup>14</sup>
- The patient should be informed that ARV drugs are not licensed for PEP use and do not guarantee 100% protection
- Baseline HIV screening test at PEP presentation and follow-up visits at month 1, 3, and 6 should be arranged to detect those already infected with HIV or those who are seroconverting. nPEP recipients should be further screened for other sexually transmitted infections (STIs), including syphilis, Hepatitis B and C.

ARV drugs used for PEP/nPEP have significant toxicities. The most common are GI symptoms (nausea, vomiting), which result in almost half of PEP recipients prematurely terminating treatment due to unacceptable side effects.

nPEP should only be considered as one of the several methods of HIV prevention. From a public health perspective nPEP has been shown to have a limited contribution to the numbers of new HIV infections averted. An Australian retrospective study of 1552 nPEP recipients estimated that the number of new HIV infections prevented ranged between 0.9 and 9.2.<sup>15</sup> In the same six-year period there were 1,138 new infections reported in the geographical area covered by the study. A French study with 8958 individuals showed similar estimations (7.7 new infections prevented over a 4-year period).<sup>16</sup>

Several studies have found that nPEP is cost-effective when prescribed in high-risk settings (unprotected receptive anal intercourse with source being HIV+) as well as occupational exposures.<sup>16–18</sup> However, these studies assumed that provision of nPEP prevented lifetime costs associated with HIV infection. Such an assumption is true only if there are no ongoing exposure risks. Unfortunately, it has been shown that receipt of nPEP among the MSM population in Sydney was associated with a three-fold increased risk of subsequent HIV seroconversion due to continuing risk behaviors.<sup>19</sup>

There are some controversies around enhanced safe-sex messages, counseling, and health promotion to minimize risk of seroconversion when a patient presents for nPEP. In addition, there is uncertainty of how ARV therapy use within the source should affect the risk assessment. In HIV+ patients who are on therapy, those with an undetectable plasma viral load range from 75% in the U.S. to 95% in Australia.<sup>20,21</sup> Plasma viral load is certainly one of the strongest correlates of HIV transmission among serodiscordant couples. People with an undetectable plasma viral load have usually an undetectable viral load in semen.<sup>22,23</sup> Theoretically, if the source is known to be on ARV therapy (ART) with an undetectable viral load, then their risk of transmission would be negligible and nPEP would not be warranted. However, this situation has not been addressed with nPEP guidelines.

#### Keynotes:

- Inform patients that evidence that PEP prevents HIV infection is limited;
- Calculate risk of HIV transmission before prescribing PEP;
- Prescribe PEP for high-risk exposures (usually greater than 0.000067 [1/15,000]);
- There is no evidence that a two- or three-drug regimen is better than one drug; and
- ARV drugs with the best evidence are: AZT and tenofovir.

### Pre-exposure Prophylaxis for Women with Topical Microbicides Containing ARV

HIV prevention strategies that women can use and control remain a pressing priority. Microbicides are products that can be applied to the vagina (or rectum) with the intention of reducing the acquisition of STIs, including HIV. They are reviewed elsewhere in this volume (see Chapter 13, “Microbicides for Prevention of Sexually Transmitted Infections” by GP Talwar and Kavita B. Garg). However, three “first-generation” microbicides have already failed efficacy trials, and two-cellulose sulfate and nonoxonyl-9 actually increased women’s risk of infection.

Nevertheless, Abdool Karim at the Centre for the AIDS Program of Research in South Africa (CAPRISA), Durban, and her colleagues tested a 1% vaginal gel formulation of the ARV drug tenofovir between 2007 and 2009.<sup>24</sup>

The CAPRISA 004 trial assessed effectiveness and safety of a 1% vaginal gel formulation of tenofovir, a nucleotide reverse transcriptase inhibitor, for the prevention of HIV acquisition in women. A double-blind, randomized controlled trial was

conducted comparing tenofovir gel ( $n = 445$ ) with placebo gel ( $n = 444$ ) in sexually active, HIV uninfected 18- to 40-year-old women in urban and rural KwaZulu-Natal, South Africa. HIV serostatus, safety, sexual behavior, gel, and condom use were assessed at monthly follow-up visits for 30 months. HIV incidence in the tenofovir gel arm was 5.6 per 100 women-years, i.e., person time of study observation, (38/680.6 women-years) compared with 9.1 per 100 women-years (60/660.7 women years) in the placebo gel arm (incidence rate ratio = 0.61;  $p = 0.017$ ). In high adherers (gel adherence > 80%), HIV incidence was 54% lower ( $p = 0.025$ ) in the tenofovir gel arm. In intermediate adherers (gel adherence 50 to 80%) and low adherers (gel adherence < 50%) the HIV incidence reduction was 38% and 28%, respectively. Tenofovir gel reduced HIV acquisition by an estimated 39% overall, and by 54% in women with high gel adherence. No increase in overall adverse event rates was observed. There were no changes in viral load and no tenofovir resistance in HIV seroconvertors. A coitally related dosing strategy was selected to achieve high adherence, based on in-depth consultations with the communities involved. Sexual behavior data showed that women in the key study population had infrequent high-risk sex with migrant partners. Monkey challenge data and perinatal transmission studies informed the timing of doses in relation to sex. The “before and after” sex doses were modeled on the timing of nevirapine in its proven strategy for preventing mother-to-child HIV transmission. Women were requested to insert one dose of gel within 12 hours before sex and a second dose of gel as soon as possible within 12 hours after sex and no more than two doses of gel in a 24-hour period. Hence, the dosing strategy was referred to as “BAT24.” The latter restriction was imposed due to the lack of human safety data on more than two doses of gel per day. In addition, in CAPRISA, use of tenofovir gel reduced herpes simplex virus-2 incidence by 51% versus placebo, i.e., a “dual effect,” likely to be very important (unpublished data).

It is not possible to derive from this study any conclusions on the safety and effectiveness of tenofovir gel for anal sex. Similarly, it is not possible to make any conclusions on the effectiveness of tenofovir gel in relation to the timing of gel applications because when the gel was applied, BAT 24 was usually followed.

Another study, VOICE, which began enrolment in August 2009, will compare the safety, acceptability, and effectiveness of daily oral versus topical PrEP strategies in 5,000 women in South Africa, Uganda, Zimbabwe, and Zambia (NCT00705679). It will also be the first to provide comparative data on the 2 methods of administration.

### Pre-exposure Prophylaxis of HIV with Oral ARV

The earlier animal models<sup>2-4</sup> assessed efficacy of PEP after intravenous challenge with virus in macaques. In sexual transmission, HIV first replicates at a low level at the mucosal point of entry in the new host.<sup>25</sup> It is therefore possible that effective PrEP can exploit this brief period of virus vulnerability,

if founder populations of infected cells do not expand sufficiently to establish a self-propagating infection.

Recently researchers have created “humanized bone marrow-liver-thymus mice,” and shown that their female reproductive tract is not only susceptible to intravaginal infection by HIV-1, but can also be completely protected by PrEP with emtricitabine (FTC)/tenofovir (TDF).<sup>26</sup>

In addition, oral or subcutaneous PrEP with FTC, TDF, or both, has been shown to protect against rectal SHIV transmission in a rhesus macaque model that closely resembles human transmission.<sup>27,28</sup>

In humans, three clinical studies of oral PrEP have been completed to date. The first study<sup>29</sup> was conducted among women in Ghana, Nigeria, and Cameroon, and was intended as an efficacy study of oral tenofovir. Although the study was terminated early for political reasons, the data supported the safety of daily tenofovir. Another placebo-controlled safety study of once-daily oral tenofovir has recently been completed by CDC in 400 MSM, with a favorable result.<sup>30</sup>

Recently, Grant and colleagues,<sup>31</sup> reported that the combination of emtricitabine and tenofovir disoproxil fumarate (FTC-TDF) (Truvada), administered orally on a daily basis by men and transgender women (born male) who have sex with men, provides partial protection from HIV infection. The trial, called the Pre-exposure Prophylaxis Initiative (iPrEx) study, was a placebo-controlled, double-blind, randomized trial involving 2,499 subjects in the Americas, South Africa, and Thailand. Of the 100 incident infections, 64 occurred in the placebo group and 36 in the FTC-TDF group, for an estimated efficacy of 44% with a 95% confidence interval of 15 to 63. In the FTC-TDF group, the study drug was pharmacologically detected in 51% of subjects who remained free of HIV infection but in only 9% of those who became infected. Thus, exposure to FTC-TDF was associated with a reduction in HIV acquisition, which supports the biologic plausibility of the primary result. In fact, a small substudy found that risk of infection plummeted by 92% in people who had measurable drug levels in their blood.

The results of the Pre-exposure Prophylaxis Initiative study also reveal real challenges and raised many concerns.<sup>32,33</sup> First, the association between self-reported drug adherence and pharmacological detection of the study drug was very poor, which underscores the need for better reporting tools to predict drug adherence. Second, although renal insufficiency and decreases in bone mineral density were seen in a relatively small fraction of subjects and was reversible on drug discontinuation, this finding raises both safety and monitoring concerns regarding possibly cumulative toxic effects associated with large-scale exposure of at-risk persons to daily FTC-TDF therapy for an extended period. The side effect profile for FTC-TDF was probably diluted, given the reported medication-compliance issues, and thus would probably be more substantial with full compliance. The study also raises cost-effectiveness concerns, in that 1,220 subjects were prescribed medication for up to 2.8 years in order to prevent an estimated 28 infections, or expressed another way; treating 43

people to stop one infection. Furthermore, the fact that FTC-TDF (Truvada) is patent-protected, and therefore an expensive medication, raises questions as to whether its use as a preventative measure should be funded by the government, private health industry, or by the individual. It should be noted that this study was conducted in highly supportive environment when specific high-risk groups had access to counselling (safe sex) and health-promotion activities (condom use) which may be not a case in real-world settings, different populations and geographical locations. There is concern that the widespread use of PrEP might lead people to take more risks than they would otherwise, offsetting the benefit of the intervention. There is always a risk for evolution of multi-drug resistant HIV strains.

Other studies of PrEP are ongoing, in IDU (Bangkok), women in Africa (VOICE-see earlier section on microbicides), and FEMPrEP, (a phase III trial to evaluate the safety and effectiveness of daily oral TDF/FTC), all of whose results should further guide recommendations in this field.

There are currently no guidelines for prescribing PrEP, although, CDC has published interim guidance.<sup>34</sup>

## Effective Treatment of Infected Persons to Reduce HIV Transmission to Their Partners

Viral load is the major determinant governing the risk of sexual transmission in HIV-1 discordant couples,<sup>35</sup> and therefore, effective ARV should dramatically reduce transmission rates. In a meta-analysis of data from five studies, some of which were unpublished, investigators reported only five cases of HIV-1 transmission from patients receiving ART to sexual partners during 1098 person-years of follow-up, which is consistent with an infection rate of 0.19–1.09 per 100 person years.<sup>36</sup>

In 2010, Donnell and colleagues (the Partners in Prevention HSV/HIV Transmission study team)<sup>37,38</sup> reported the results of a study nested within a placebo-controlled trial, which showed no effect of Herpes simplex virus-2 treatment on HIV transmission in nearly 3,400 African serodiscordant heterosexual couples. As one in 10 participants started on ARV during the trial, the investigators were able to compare HIV transmission before and after starting treatment. HIV incidence was 2.24 per 100 person-years before starting ARV (102 transmission events) and 0.37 per 100 person-years after starting treatment (one event which probably occurred before full suppression of viral load in the index partner), yielding an adjusted incidence rate ratio of 0.08, a 12-fold reduction in transmission.

Investigators in Switzerland also reviewed transmission rates among discordant couples in their country, concluding that in a monogamous relationship, with no concurrent sexually transmitted infections, the risk of HIV transmission was “negligible.”<sup>39</sup> Another observational cohort study from Uganda reported similar data. Free ARV programs were initiated in 2004, and the rates of HIV-1 transmission before and after the programs began, in the Rakai district, were measured.<sup>40</sup> Two hundred and fifty HIV-1 discordant couples were followed between 2004 and

2009 and 32 HIV-1-positive partners initiated ART. Forty-two HIV-1 transmissions occurred over 459.4 person-years prior to ART initiation, incidence 9.2/100 person-years (95% CI, 6.59–12.36). In 32 couples in which the HIV-1 index partners started ART, no HIV-1 transmissions occurred during 53.6 person-years. The 95% confidence interval for the incidence rate difference was -11.91 to -6.38 ( $p < 0.0097$ ). Couples reported more consistent condom use during ART, but there was no significant difference in the number of sexual partners or other risk behaviors. Although there was a significant increase in consistent condom use following ART initiation, the reduction in risk was most likely due to the direct reduction in HIV-1 viral load in the HIV-1-positive partners on ART. These findings add to the growing body of evidence supporting the use of ART for HIV-1 prevention.

Ongoing studies such as the HIV-1 Prevention Trials Network 052 study (by NIAID) will test the hypothesis that ART can prevent HIV-1 transmission among HIV-1 discordant couples by randomizing couples in whom the infected partner has a CD4 cell count of 250–550 cells per microliter to either start ARVs immediately, or wait until the CD4 count drops below 250 cells per microliter<sup>41</sup>; results are expected in 2014. This trial will provide useful data on long-term measures of efficacy of ART among discordant couples, adherence when ARV are initiated earlier, incidence of drug resistance, and potential risk compensation.

### Reduction of the HIV Epidemic by Widespread Use of Effective ARV in Infected Individuals

The “treatment as prevention” strategy aims to reduce community viral load and assumes that this will reduce HIV transmission. Indeed, lower rates of HIV diagnosis in San Francisco and British Columbia have accompanied lower viral loads in HIV-infected people undergoing viral tests,<sup>42,43</sup> and in Taiwan, rapid expansion of ARV was associated with a 50% reduction in new HIV diagnoses.<sup>44</sup> Granich and colleagues<sup>45</sup> have developed a statistical model predicting that universal testing of all sexually active adults and immediate ARV therapy (regardless of CD4 count) could have a major effect on generalized epidemics.

However, Hosein and Wilson<sup>46</sup> make pertinent comments on the situation among MSM in France, with continuing high incidence,<sup>47</sup> despite high uptake of highly active antiretroviral therapy, and where 92% of treated patients achieve an undetectable viral load. Similar situations pertain among MSM in Sydney<sup>19,48</sup> and in Amsterdam.<sup>49</sup> They suggest that the preventative role of treatment may be different in MSM to heterosexuals and IDU, because of higher biological transmission rates, and the sexual milieu of MSMs. As mentioned in the French study, such circumstances include a high HIV prevalence, increased rates of unprotected anal sex with more partners, and increased prevalence of STIs.

Thus, merely intensifying a treatment uptake as prevention strategy for MSM without addressing other co-existing issues at the

individual or community level may not lead to sustained changes in some HIV epidemics. As the majority of HIV transmissions worldwide occur within the heterosexual community, selective use of ARV medications may have differing outcomes on HIV transmission in different populations, e.g., in countries where transmitted drug resistance is common, where sub-optimal first-line ARV use has created a pool of resistance to these agents, or where ARV roll-out has not reached the majority of infected people.

### Conclusions

ARV drugs alone, while having a dramatic impact at the individual level, are unlikely to have a significant impact on HIV transmission at the population level unless accompanied by a range of additional strategies, such as, universal access to testing and treatment, education on risk behaviors, and removing barriers to condom use and needle/syringe exchange programs. All of these strategies unfortunately highlight deficiencies in the way health and HIV is managed globally. The greatest challenge in reducing HIV transmission rates is not necessarily achieved through biological interventions such as ARV alone but the more difficult task of changing human behavior.

## Introduction

The first case of primary HIV infection was described in 1984 in a nurse from the UK who had received an accidental needle-stick injury.<sup>1</sup> The HIV can also be transmitted to humans via unprotected sexual intercourse with an infected individual, transfusion of infected blood, injection drug use with contaminated needles and syringes, or from infected mother to the child at the time of child birth or breast feeding. The amount of HIV in the blood gets very high within a few days or weeks after HIV infection. Some people get a flu-like illness. This first stage of HIV disease is called “acute HIV infection” or “primary HIV infection.” Our understanding of the pathophysiology of primary HIV infection and the clinical signs and symptoms has advanced considerably in the years following this initial case. A better understanding of the events surrounding primary HIV infection may contribute to vaccine development, clinical treatment, and improved strategies to prevent transmission. This chapter will focus on the pathophysiology, clinical presentation, diagnosis, and treatment of primary HIV-1 infection, and HIV is used in the whole chapter to refer HIV-1.

## Pathophysiology

Despite the importance of pathophysiologic events surrounding primary HIV infection, data are limited from human studies. The majority of studies have been performed in rhesus macaques, experimentally infected with the monkey equivalent of HIV, simian immunodeficiency virus (SIV). These studies have revealed that after endocervical exposure, only a small number of infected cells were detected in the first three days close to the site of exposure. T cells in the lamina propria represented the predominant cell population at this early stage.<sup>2</sup> The majority of the HIV transmissions worldwide occur across a mucosal surface such as the anorectal mucosa, vaginal mucosa and, less frequently, the oral mucosa.<sup>3,4</sup> HIV-receptive cells have been found in the lamina propria of rectal, cervicovaginal, foreskin, urethral, and oral epithelia in primate models.<sup>5</sup> Indeed, certain characteristics of the mucosal compartment render it extremely permissive to

HIV-1 infection and supportive of HIV-1 replication. Compared with circulating lymphocytes, a greater percentage of mucosal cells express the CCR5 chemokine coreceptor.<sup>6,7</sup> The study of the human gastrointestinal (GI) tract during acute HIV-1 infection is challenging. Consequently, initial work in this area emerged from the SIV-macaque model. A striking depletion of intestinal CD4+ T cells was noted in macaques within days of SIV infection, at a time when little or no CD4+ T cell depletion was evident in the peripheral blood or lymph nodes.<sup>8</sup> Furthermore, intestinal CD4+ T cell depletion occurred regardless of whether viral inoculum was intrarectally or intravenously delivered.<sup>8</sup> These studies were subsequently extended to demonstrate that GI lymphocyte depletion occurs in all stages of SIV.<sup>9</sup> Studies by Mattapallil and colleagues<sup>10</sup> and Li and coworkers,<sup>11</sup> demonstrate rapid infection and destruction of GI memory CD4+ T cells within days of infection with SIV. In recent studies on humans, it has been demonstrated that during acute HIV-1 infection, a preferential and profound depletion of CD4+ T cells occurs within the GI tract.<sup>12–14</sup> Over the subsequent days, the infection spreads to other cell types, including dendritic cells (DCs) and macrophages, with the majority of infected cells represented by resting CD4+ T cells. Resting T cells constitute a significant reservoir of latent HIV that may be activated to complete the replication cycle upon activation of the host cell. It has been shown *in vivo* that HIV can infect T cells that are not fully activated. During the course of HIV infection, integrated and replicative-competent provirus can be found in a population of resting memory CD4+ T cells (1,2) and the frequency of these cells tends to remain stable for years, decreasing only minimally with the administration of combination antiretroviral therapies.<sup>15,16</sup> DCs are believed to play a key role in the dissemination of HIV following local infection. DCs provide a highly specialized function whereby HIV antigens encountered in peripheral tissues can be brought into contact with T cells in draining lymph nodes and ultimately generate an immune response to these antigens. HIV is capable of entering immature DCs at the epithelial and mucosal surfaces and undergoes limited replication until DCs encounter T cells in lymphoid tissues.<sup>17</sup> In addition to their

role in antigen presentation, DCs may be capable of facilitating the spread of HIV through the unique lectin called DC-SIGN. When bound to DC-SIGN, HIV can remain viable for days potentially providing an additional mechanism for transport to the regional lymph nodes.<sup>18</sup>

Following the initial sequence of events, systemic dissemination occurs, with HIV-1 being culturable from plasma within five days of initial infection.<sup>19</sup> In animal models productive infection in cervicovaginal tissues and hematological dissemination is followed by systemic infection between six and 10 days with peak viral infection in other tissues. Estimates in humans of the incubation time from mucosal infection to initial viremia range from 4 to 11 days.<sup>20</sup> After initial infection, a rapid rise in plasma viremia ensues with dissemination of the virus to lymphoid organs and trapping of virus by follicular DCs.<sup>21–23</sup> This stage of infection may be particularly important from a public health perspective, as it is likely to be accompanied by high levels of replicating virus, and consequently, high infectivity among individuals who may not be aware of their infection status.<sup>24</sup> Sexual transmission of HIV-1 may be enhanced at this stage by breaks in the genital mucosa and increased inflammation due to the presence of genital ulcer disease, urethritis, or cervicitis.<sup>25</sup>

Transmitted HIV-1 viruses are typically macrophage-tropic and lack the ability to form multinucleated syncytia in tissue culture.<sup>26,27</sup> Virus entry requires the binding of glycoprotein 120 to the CD4 molecule on susceptible cells in conjunction with binding to the coreceptor for macrophage-tropic strains, CCR5.<sup>28,29</sup> The binding of CD4 to gp120 results in a structural change, which exposes a coreceptor binding site. Following coreceptor binding, further structural rearrangements occur, predominantly in gp41, which are thought to be sufficient to facilitate viral fusion and cell entry. The ability of HIV to vary the conformational structure of the envelope protein and coreceptor may play a role in immune evasion by the HIV. T cell-tropic strains of HIV-1 seen in acute but predominantly in chronic infection require the coreceptor CXCR4 for entry.<sup>30</sup> These different strains of the HIV-1 are now referred to as R5 and X4 viruses, respectively.<sup>31</sup> Individuals who are homozygous for a 32-bp deletion in CCR5 (CCR5Δ32) are relatively resistant to infection with R5 strains of HIV-1.<sup>32,33</sup> Rare cases of transmission of X4 viruses have been reported in individuals homozygous for CCR5Δ32.<sup>34,35</sup>

Following the establishment of HIV-1 infection in the lymphoid tissues, peak viremia occurs an average of six to 15 days after the onset of symptoms, with viral load levels in the range of one to 70 million copies/ml.<sup>36,37</sup> Over the following weeks, the viral load falls by several orders of magnitude despite the absence of neutralizing antibody.<sup>38</sup> The early control of HIV replication at this stage is believed to be largely due to the cellular immune response to the virus.<sup>39</sup> A temporal relationship has been shown in humans between the appearance of HIV-1 specific cytotoxic T lymphocytes (CTLs) and declining viral load.<sup>40,41</sup> Data from Indian patients infected with subtype C virus suggest that patients exhibiting consistent subtype-specific T cell responses to

HIV-1 gag might have better control of viral replication in early HIV infection.<sup>42</sup> Many of the clinical symptoms observed during primary infection may reflect the immune response to the virus with the ultimate resolution of symptoms coincident with the decrease in plasma viral load.<sup>43</sup> After the fall in plasma viral load, a viral set point is established normally around 12 to 18 months after infection.<sup>44</sup> The absolute level of the viral set point and early viral trajectory have been correlated with the duration of AIDS-free survival time.<sup>44,45</sup>

Numerous studies among patients infected with subtype B virus have suggested that the rate of clinical progression to AIDS following initial infection may depend upon early immunologic and virologic events occurring soon after primary HIV infection.<sup>45–47</sup> A recent study of subtype C infected seroconverters from India suggests that the pattern of disease progression may be different in the Indian setting. The authors found that the viral set point reached following infection was similar among Indian patients to that seen in the North American setting but the median trajectory of increasing viral load in Indian seroconverters was greater than what has been reported in untreated seroconverters from the US.<sup>48</sup> This discrepancy may be explained by a number of factors. Low socioeconomic status and limited access to healthcare has been associated with a worse survival among HIV-infected patients in Canada and the UK.<sup>49,50</sup> Other factors, such as the high rate of endemic diseases like tuberculosis, and parasitic diseases may be a factor in the altered disease progression observed among Indian seroconverters.<sup>51–54</sup> Additional host factors which may affect disease progression in resource poor setting include the level of immune activation in the population and the presence of micronutrient deficiencies.<sup>55–57</sup>

## Clinical Presentation

If present, the signs and symptoms of primary HIV infection usually appear within days to weeks following exposure.<sup>58</sup> The primary HIV syndrome may last from a few days to more than 10 weeks with the majority of individuals experiencing symptoms for less than 14 days.<sup>59</sup> The three most common presenting symptoms include fever, fatigue, and rash.<sup>59</sup> Other reported symptoms include headache, myalgia, pharyngitis, nausea, vomiting, diarrhea, and night sweats.<sup>60</sup> A maculopapular skin rash seen in primary HIV infection usually involving the face, trunk, and limbs, which may also involve palms and soles, is helpful in making the diagnosis. Primary HIV disease may rarely present with genital ulcers.<sup>61</sup> Important clinical manifestations of acute HIV infection are summarized in Table 72.1.

The non-specific constellation of symptoms associated with primary HIV infection presents a diagnostic challenge to healthcare providers.

Many of the studies investigating the signs and symptoms of primary HIV infection have relied on the referral of symptomatic high-risk persons resulting in an important element of detection bias. A nested case-control study examining the clinical signs of primary HIV infection among Indian patients revealed fever, joint

**Table 72.1:** Common Symptoms Associated With Acute HIV Syndrome

Symptomatic symptoms	50–90%
Fever	96%
Adenopathy	74%
Pharyngitis	70%
Morbilliform, maculopapular rash	70%
Diarrhea	32%
Headache	30%
Nausea/vomiting, neurological, e.g. aseptic meningitis	27%
Genital ulcers	10%
	Rare

Adapted from The 2002 Abbreviated Guide to Medical Management of HIV Infection.

pains, night sweats, and inguinal adenopathy to be significantly associated with p24 antigenemia.<sup>62</sup> Of the 58 subjects with recent HIV infection, 27 (47%) reported fever, joint pains, and/or night sweats. A rash, which has been proposed as an important clinical sign in many of the earlier studies, was only found in 2 (3.5%) subjects in this study. The high rate of symptoms observed among the control patients in this study made it difficult to distinguish those with acute HIV infection from other clinic patients. In the uncommon occurrence of genital ulcers in PHI, herpes simplex virus infection should be considered in differential diagnosis. Syphilis should also be excluded especially in areas where it is prevalent. A recent cohort study from Uganda found that only a minority of subjects experienced a seroconversion illness (five of 27 or 18.5%), which was similar to the rate observed among control subjects (four of 22 or 18.2%).<sup>63</sup> The authors attribute the lack of seroconversion illness to the possible immunological differences in the responses to HIV-1 infection in African populations and also the high background rate of other illnesses like malaria which make it difficult to distinguish the seroconversion illness from other illnesses. The non-specific nature of symptoms surrounding primary HIV infection and the high rate of other infectious diseases, which may mimic the seroconversion illness, make it prudent to include primary HIV infection in the differential diagnosis of any patient presenting with a non-specific flu-like illness and recent high-risk behavior. An accurate history of exposure risk is also an essential tool in identifying individuals at risk for primary HIV infection who may not experience any symptoms suggestive of a seroconversion illness. Unfortunately, diagnosis of acute HIV infection is an uncommon event, and the advantages of such early diagnosis are not always apparent to the patient or even to the provider. Understanding the association between symptoms, initial HIV viremia, and ultimate viral set point may help determine treatment decisions for such patients. The incubation period and duration of acute retroviral syndrome have been associated with progression to AIDS.<sup>64</sup>

## Diagnosis

Recognizing primary HIV infection has important implications for controlling the spread of the epidemic. It has important clinical and public health implications. The acute infection may be the only opportunity to diagnose HIV before the patient

presents with AIDS-defining conditions. It also allows for early treatment intervention if warranted or to enroll the patients into therapeutic studies. However, more emphasis has been put on the infectiousness in early infection. The early stages of HIV are particularly important due to the high viral load in blood and genital secretions and lack of awareness of infection characteristic of this period.<sup>65</sup> Two studies have examined this period in mathematical models of transmission and have found that the primary stage has an infectivity rate much higher (50–100 fold) than subsequent periods following infection.<sup>66,67</sup>

The laboratory diagnosis of primary HIV infection can be made by the demonstration of a positive virologic test in the absence of HIV-specific antibodies. The detection of p24 antigen in serum or plasma has been recommended for the diagnosis of primary HIV infection during the seroconversion window period and has been shown to be 88.7% sensitive and 100% specific in one cohort study.<sup>68</sup> HIV RNA assays have been shown to have a sensitivity of 100% and specificity of 97%, but their application to the diagnosis of primary HIV infection is limited by their feasibility, cost, and potential for false positive results making confirmatory testing necessary.<sup>69</sup> False positive results may be limited by the use of repeat testing and imposing a threshold of greater than 2000 copies/ml.<sup>70</sup> To reduce the cost of HIV RNA assays in the diagnosis of acute HIV infection, the use of pooled specimens was considered in a low prevalence, high-volume clinic setting. This testing strategy identified approximately 10% additional infections compared with the conventional HIV antibody testing strategy, and may offer an improved algorithm for identification of primary HIV infection in low-prevalence settings with high volume laboratory testing.<sup>71</sup> The current cost and pros and cons of various options for patients in developing countries are summarized in Table 72.2.

The most recent tool which has become available to identify individuals recently infected with HIV-1 has been the use of the sensitive/less-sensitive (detuned) enzyme immune assay strategy.<sup>72</sup> This strategy has been shown to distinguish recent from chronic HIV-1 infection among individuals with subtype B infection but only after seroconversion has occurred, limiting its application.

**Table 72.2:** Testing Options and Costs in Developing Countries

Test	Approximate cost (excluding labor), US\$	Advantages	Disadvantages
EIA*	5	Inexpensive, simple	Not useful for primary infection
p24	25	Simple	Moderately expensive
RT-PCR Pooled	100	Sensitive	Technologically complex, False positives, requires confirmation
PCR	20	Low cost, sensitive	Cost increases in high prevalence populations, requires confirmation

\*Free under national program of many countries.

The detuned enzyme immune assay is currently under evaluation in other settings where diverse subtypes are transmitted and may provide a useful tool in future for the diagnosis of early HIV infection in patients who are already HIV-antibody positive.

Despite the importance of recognizing and diagnosing primary HIV infection, mandatory testing for HIV has been discouraged by a number of authorities including the American Medical Association.<sup>73</sup> Mandatory testing of certain at risk groups such as pregnant women could result in an avoidance of care with the ultimate result of increasing HIV transmission. However, introduction of routine testing of all pregnant women (through counseling and informed consent) under the Prevention of Parent to Child Transmission program of National AIDS Control Organisation in India has started showing its positive effects with the drop in mother-to-child transmission rates. Numerous reports have highlighted the success of voluntary counseling and testing programs in diagnosing HIV infection with the adoption of these programs by the majority of healthcare policy makers.<sup>74,75</sup>

## Treatment

The period following initial infection with HIV is characterized by a high viral load, rapid virus turnover, and widespread dissemination.<sup>36,76</sup> The most homogeneous virus population in the setting of a mostly intact immune system also characterizes this period. It would appear that this time period would represent an opportunity to preserve the immune system, and attack the virus with the most effective antiviral pressure. It is unclear whether antiretroviral therapy should be initiated at PHI and for what duration of time. The Spartak study will elucidate whether a short period of ART initiated at primary HIV infection will delay the time to CD4 T cell count below 350 cells. Some early reports have been encouraging and supportive of this view showing that patients treated early in infection can recover or retain HIV-specific CD4+ T cell responses and also maintain an effective CD8+ T cell response.<sup>77,78</sup> However, concern has been raised by some investigators that early initiation of therapy does not allow for the immune system to generate a full response to HIV antigens.<sup>79,80</sup> The breadth and magnitude of CTL responses was less in those treated before seroconversion, but the viral diversity was also significantly less in this group compared to those treated after seroconversion. The authors of this study concluded that early treatment resulted in a more narrowly directed CTL response with stronger T helper cell responses resulting in a less diverse virus population. A subsequent study of a large seroconverter cohort in Australia found that early antiretroviral treatment of primary HIV infection resulted in better early virologic responses but no significant difference in immunologic responses (based on changes in CD4+ cell count).<sup>81</sup> Although these early reports are encouraging, more research is needed into the long-term benefits of early treatment before any clinical recommendations can be made. Theoretical advantages supporting early treatment include the potential to decrease the

severity of acute disease, the potential to alter the viral set point and ultimately alter the rate of disease progression, reduce the rate of viral mutation, preserve immune function, and possibly reduce the risk of HIV transmission. These theoretical benefits are balanced by the potential risks of therapy, which include drug toxicity, cost, side effects, adverse effects on quality of life, potential early development of drug resistance, and the burden of long-term therapy. Currently in the North American setting, routine highly active antiretroviral therapy (HAART) treatment of patients with acute HIV infection is not recommended. It is recommended that individuals found to be acutely infected with HIV be referred to specialists for possible enrolment in early treatment studies.

Considerable interest has been generated in recent years to the potential for structured treatment interruption of HAART in the primary HIV infection period to facilitate the autoimmunization of infected individuals with the goal of maintaining viral suppression in the absence of HAART. Eight patients from Boston were treated with a structured treatment interruption regimen and were able to maintain viral suppression in the absence of drug therapy.<sup>82</sup> Additional studies in macaques acutely infected with SIV illustrated that intermittent interruption of therapy is the factor responsible for boosting immunity.<sup>83</sup> Subsequent early reports from human trials have been less encouraging with spontaneous control of viremia observed in only one-third of cases after four cycles of two months off therapy.<sup>84</sup> Currently, clinical trials of structured treatment interruption are ongoing to assess the benefit of this new approach to the management of primary HIV infection. The outcomes from these studies will be required before any recommendations regarding this approach to therapy can be made.

## Conclusion

Acute infection caused by HIV gradually destroys the immune system. Primary HIV infection represents a period of rapid change in virologic and immunologic parameters. This magnitude of change is often not translated into a recognizable clinical syndrome creating a diagnostic challenge for healthcare practitioners. Treatment with HAART during this early period may not offer definite clinical benefit and is not routinely recommended. Additional clinical studies will be required to determine whether HAART treatment of acute HIV infection is actually beneficial to the patient. However, the period immediately following HIV infection represents an important window of opportunity from a public health perspective characterized by individuals with high infectivity, who are often unaware of their infection status. Thus, identification and counseling of patients with acute HIV infection may be important for preventing the spread of HIV infection to their unaware sexual contacts. This highlights the importance of adequate resources for voluntary counseling and testing programs to help control the spread of the HIV epidemic.

## Summary

Improving the diagnosis of acute HIV-1 infection among healthcare providers remains a priority. It should lead to preventative measures to prevent onward transmission and further research into the mechanisms of HIV-1 transmission. It should also allow to enrol patients into care and decrease the number of late presenters. The impact of very early initiation of ART remains under investigations, and very early cohorts need to be further characterized in term of the potential for maximal immune reconstitution and decrease of viral reservoirs. This should in turn allow to implement new treatment strategies for investigating the potential for virological control post-stopping treatment.

## Introduction

HIV infection encompasses a spectrum of clinical features ranging from an acute syndrome with primary infection via a prolonged asymptomatic state to advanced disease. The infection relentlessly progresses in untreated patients even during the clinically latent stage. The spectrum of illnesses that one observes changes progressively as the CD4<sup>+</sup> T cell count declines (Fig. 73.1). This correlates with the degree of immunosuppression.

The systemic symptoms in HIV patients can be categorized into the following groups based on the CD4<sup>+</sup> lymphocyte count<sup>1</sup>:

- Greater than 500 cells/ $\mu$ L, causes of systemic symptoms are less likely to be related to HIV infection.
- Between 200 and 500 cells/ $\mu$ L, frequent infections such as bacterial pneumonia and sinusitis occur, however, these are not considered as opportunistic infections (OIs).
- Less than 200 cells/ $\mu$ L, a host of OIs such as cytomegalovirus (CMV), *Strongyloides stercoralis*, *Candida* spp., and *Cryptosporidium parvum* occur.

Common infections can occur with uncommon clinical presentations during this late stage of HIV disease.

## Definition

**An OI is an infection caused by pathogens that usually do not cause disease in someone with healthy immune system.** The “opportunity” arises with the compromise of the immune system such as in AIDS. This may also reactivate latent infections which were probably kept in check by the healthy immune system. In this chapter we will deal with OIs in HIV infection/AIDS.

## Pathogenesis

The precipitation of OIs in HIV positive patients is thought to be as a result of severe qualitative and quantitative defects of the CD4<sup>+</sup> T helper lymphocytes.<sup>2,3</sup> The central pathogenic feature of HIV infection is the depletion of CD4<sup>+</sup> T lymphocytes and is largely responsible for the profound immunodeficiency characteristic of the late stages of HIV disease.<sup>4</sup> Multiple mechanisms have been shown to contribute to the HIV-1-associated loss of CD4<sup>+</sup> T cells in HIV-1-infected individuals, among which the HIV-1-induced apoptosis of bystander uninfected cells is considered to be the most important.<sup>5-8</sup> Several virally encoded proteins, including the envelope protein gp120, Tat, and Vpr, have been implicated in this process.<sup>6,9,10</sup> It has recently been seen that CD45, a membrane tyrosine phosphatase, regulates the HIV gp120 mediated apoptosis.<sup>11</sup>

The qualitative defects of the CD4<sup>+</sup> cells weaken the helper role of these cells, both in relation to the monocyte macrophage system and B cell immunoglobulin production.<sup>3</sup> This hampers the chemotaxis and intracellular killing capacity of these cells.<sup>12-14</sup> Thus, HIV-infected individual are predisposed to infections with *Staphylococcus aureus*, *Pseudomonas aeruginosa*, and gram-negative enteric bacteria.

B cell abnormality may present as an increase in the spontaneous secretion of immunoglobulins or as impaired response to a variety of antigens<sup>15</sup> making an individual prone to infection with encapsulated bacteria such as *Streptococcus pneumoniae* and *Haemophilus influenzae*. The lack of antibody response to new infections can be devastating in children with perinatally acquired HIV infection who had no opportunity to develop antibody to infecting pathogen before developing B cell dysfunction.

**Fig. 73.1:** Opportunistic infections in HIV-infected patients in relation to CD4<sup>+</sup> lymphocytes counts.

## Pattern of Infection

OIs were the principal cause of morbidity and mortality before the widespread use of potent combination antiretroviral therapy (ART) in patients infected with HIV. The use of chemoprophylaxis, immunization, and better strategies for managing acute OIs in the early 1990s, contributed to improved quality of life and improved survival.<sup>2</sup> The widespread use of ART starting in the mid-1990s had the most profound influence on reducing OI-related mortality in HIV-infected persons.<sup>16–23</sup> (HOPS & CASCADE study)

OIs, however, continue to cause considerable morbidity and mortality for three primary reasons:

- Many patients seek medical care only when an OI becomes the initial indicator of their disease as they are **unaware** of their HIV infection.
- Certain patients are aware of their HIV infection, but do not take ART because of **psychosocial or economic** factors; and
- Certain patients are prescribed ART, but fail to attain adequate virologic and immunologic response because of factors related to **adherence, pharmacokinetics, or unexplained biologic factors**.<sup>19,24,25</sup>

Recognizing that the relation between OIs and HIV infection is bidirectional is important. HIV leads to immunosuppression that allows opportunistic pathogens to cause disease in HIV-infected persons. OIs and other co-infections that might be common in HIV-infected persons, such as sexually transmitted infections, can also have adverse effects on the natural history of HIV infection. Certain OIs are associated with reversible increases in circulating viral load,<sup>26–29</sup> and these increases could lead to accelerated HIV progression or increased transmission of HIV.<sup>30</sup> Thus, although chemoprophylaxis and vaccination directly prevent pathogen-specific morbidity and mortality, they might also contribute to reduced rate of progression of HIV disease.

In patients infected with HIV, studies have defined the correlation between CD4<sup>+</sup> cell count and occurrence of OIs.<sup>31,32</sup> These were broadly categorized into the following five groups (Table 73.1):

- Asymptomatic infection (CD4<sup>+</sup> cell count > 500/ $\mu$ L)
- Oral candidiasis and tuberculosis (CD4<sup>+</sup> cell count range 250–500/ $\mu$ L)
- Kaposi sarcoma, lymphoma, and *Cryptosporidium* (CD4<sup>+</sup> cell count range 150–200/ $\mu$ L)
- Pneumocystis carinii* (*P. jiroveci*) pneumonia, disseminated *Mycobacterium avium* complex, herpes simplex, toxoplasmosis, cryptococcosis, and esophageal candidiasis (CD4<sup>+</sup> cell count range 75–125/ $\mu$ L)
- CMV retinitis (CD4<sup>+</sup> cell count < 50/ $\mu$ L).

The spectrum of illnesses that one observes changes as the CD4<sup>+</sup> T cell count declines. The more severe and life-threatening complications of HIV infection occur in patients with CD4<sup>+</sup> T cell counts less than 200/ $\mu$ L. Table 73.2 lists some of the infections which are not opportunistic in the true sense but occur in higher frequency than in the general population.

**Table 73.1:** Mean and Median Number of CD4<sup>+</sup> Lymphocytes/ $\mu$ L for Each Category of Opportunistic Infections<sup>31</sup>

Illness	Events No.	CD4 <sup>+</sup> cells Mean	CD4 <sup>+</sup> cells Median
Asymptomatic	20	692.0	575.0
Tuberculosis	7	340.0	159.0
Oral candidiasis	22	275.6	170.0
<i>Cryptosporidium</i>	11	213.0	134.0
Herpes simplex	9	117.6	110.0
Pneumocystosis	70	111.9	70.5
<i>M. avium</i> complex	46	98.4	50.0
Toxoplasmosis	16	93.1	57.5
Cryptococcosis	11	73.2	46.0
Esophageal candidiasis	15	66.5	45.0
CMV retinitis	31	29.0	17.0
Kaposi sarcoma	43	169.5	110.0
Lymphoma	6	166.5	81.5

**Table 73.2:** Infections Occurring in Increased Frequency in HIV Seropositive Individuals

Bacterial
<i>Salmonella</i> spp. <i>Streptococcus pneumoniae</i> <i>Haemophilus influenzae</i> <i>Mycobacterium tuberculosis</i> <i>Staphylococcus aureus</i> (most common cutaneous bacterial infection) <i>Pseudomonas aeruginosa</i> (chronic leg ulcers) Sexually transmitted infections such as <i>Treponema pallidum</i> <i>Chlamydia trachomatis</i> <i>Haemophilus ducreyi</i> <i>Calymatobacterium granulomatis</i>
Fungal
<i>Histoplasma</i> spp. <i>Aspergillus fumigatus</i> <i>Nocardia</i> spp. <i>Tinea</i> spp.
Viral
Molluscum contagiosum
Parasitic
<i>Giardia lamblia</i> <i>Sarcoptes scabiei</i>

## True Opportunistic Infections in HIV Patients

### Bacterial and mycobacterial

- *Mycobacterium avium* complex (MAC, MAI)
- Tuberculosis (TB)
- Bacillary angiomatosis (cat scratch disease)

### Fungal infections

- Aspergillosis

- Candidiasis (thrush, yeast infection)
- Coccidioidomycosis
- Cryptococcal meningitis
- Histoplasmosis

### Malignancies

- Kaposi sarcoma
- Lymphoma
  - Systemic non-Hodgkin lymphoma (NHL)
  - Primary central nervous system (CNS) lymphoma
- Progressive multifocal leukoencephalopathy (PML)

### Protozoal infections

- Cryptosporidiosis
- Isosporiasis
- Microsporidiosis
- *Pneumocystis carinii* (*P. jiroveci*) pneumonia (PCP)
- Toxoplasmosis

### Viral infections

- CMV
- Hepatitis
- Herpes simplex (HSV, genital herpes)
- Herpes zoster (HZV, shingles)
- Human papillomavirus (HPV, genital warts, cervical cancer)
- Molluscum contagiosum
- Oral hairy leukoplakia (OHL)
- PML

The common OIs more relevant to the South Asia are discussed in detail below.

## BACTERIAL

### Mycobacterium Tuberculosis

The World Health Organization (WHO) estimates that TB is the cause of death for 13% of persons with AIDS.<sup>33</sup> Tuberculosis is the most common HIV-related OI in India, and caring for patients with both diseases is a major public health challenge. India has about 1.8 million new cases of TB annually, accounting for a fifth of new cases in the world—a greater number than in any other country (see Fig. 73. 2).<sup>34</sup> Two of every five persons—more than 400 million—have latent TB infection.<sup>35</sup> Tuberculosis can be expected to develop in more than half of those who are also infected with HIV. Between January and September 2006, a total of 15,000 people with suspected TB who were HIV-positive, and 16,420 who were HIV-negative were referred to such facilities by centers in the six Indian states with the highest HIV prevalence (Andhra Pradesh, Karnataka, Maharashtra, Manipur, Nagaland, and Tamil Nadu); TB was diagnosed in 22.3% and 23.9% of patients in these groups, respectively. The estimated incidence of multi-drug resistant TB is 2.4% among patients with new cases and 15% among those who have previously received treatment.<sup>34</sup> High prevalence of HIV infection among individuals with abdominal TB is seen in India.<sup>36</sup>

**Fig. 73.2:** Data are from the World Health Organization. The other high-burden countries, in descending order of number of cases, are the Philippines, Kenya, the Democratic Republic of Congo, Russia, Vietnam, Tanzania, Uganda, Brazil, Afghanistan, Thailand, Mozambique, Zimbabwe, Myanmar, and Cambodia.

The natural history of HIV-1 infection among adults in Mumbai, India, revealed that persons with TB were at 3-fold risk of an early death.<sup>37</sup> The study established the annual incidence of TB at 4.8/100 person-years and a lifetime risk of developing TB as 60% with a consistent correlation between mortality and occurrence of TB.<sup>38</sup>

Data are from the World Health Organization. The other high-burden countries, in descending order of number of cases, are the Philippines, Kenya, the Democratic Republic of Congo, Russia, Vietnam, Tanzania, Uganda, Brazil, Afghanistan, Thailand, Mozambique, Zimbabwe, Myanmar, and Cambodia

Infection with *M. tuberculosis* is almost always acquired by inhalation. A cell mediated immune response normally develops 6–10 weeks after the primary infection and is characterized by the formation of granulomas. Bacilli persist for years, a condition referred to as latent TB infection (LTBI). These people remain well unless there is a breakdown of the immunity.<sup>39</sup> TB disease can develop immediately after exposure (primary disease) or after reactivation of LTBI (reactivation disease). This latent TB is unmasked in HIV-infected people and could explain the higher incidence in the immunocompromised. It is estimated that HIV/TB co-infected individuals have an annual 5–10% chance of reactivation.<sup>40</sup>

Unlike other AIDS-related OIs, CD4+ count is not a reliable predictor of increased risk for TB disease in HIV-infected persons. In patients with relatively high CD4+ T cell counts, the typical pattern of pulmonary reactivation occurs in which patients present with fever, cough, dyspnea on exertion, weight loss, night sweats, and a chest X-ray revealing cavitory apical disease of the upper lobes. In patients

with lower CD4+ T cell counts, disseminated disease is more common. In these patients the chest X-ray may reveal diffuse or lower lobe bilateral reticulonodular infiltrates consistent with miliary spread, pleural effusions, and hilar and/or mediastinal adenopathy. Infection may be present in bone, brain, meninges, gastrointestinal tract, lymph nodes (particularly cervical lymph nodes), and viscera. Extrapulmonary disease is more common in HIV positive patients. Approximately 60–80% of patients have pulmonary disease, and 30–40% have extrapulmonary disease. Respiratory isolation and a negative-pressure room should be used for patients in whom a diagnosis of pulmonary TB is being considered. This approach is critical to limit nosocomial and community spread of infection.<sup>39</sup>

### Management of HIV and Tuberculosis Co-infection

Treatment of TB in HIV-infected patients is similar to those who are seronegative.

The gold standard for diagnosis of TB is microscopy followed by culture and drug sensitivity testing (which is not commonly available). We can use molecular diagnostics to reduce the time required for identifying the organism. It is also useful for infection control.

A high index of suspicion is needed for the diagnosis, and early diagnosis is the key. It is worthwhile to remember that the interpretation of tuberculin skin testing (TST/Mantoux) is not straightforward in patients with HIV infection. The sensitivity of TST is reduced in HIV infection.<sup>39</sup> The diagnostic tools for early diagnosis of TB include regular monitoring with clinical examination of fever, anorexia, weight loss, lymphadenopathy, diarrhea, along with FBC, ESR, Mantoux, radiography of chest, sputum AFB, sputum culture, computerized tomographic scan for CNS or abdominal TB, fine-needle aspiration cytology (FNAC) to rule out other pathogens, and polymerase chain reaction (PCR).

**DOTS (Directly Observed Therapy Short-Course)** It is the preferred form of therapy to prevent relapse and defaulters and thus prevent the occurrence of MDR-TB. The treatment of TB in HIV infected adults is similar to those for HIV uninfected adults. However, there are important exceptions. (BHIVA HIV/TB co-infection guidelines):

- Some intermittent treatment regimens are contra-indicated in HIV-infected patients because of unacceptably high rates of relapse, frequently with organisms that have acquired rifampicin resistance. Consequently, patients with CD4 counts less than 100/ $\mu$ L should receive daily or a minimum of three times weekly anti-TB treatment.
- Adherence strategies including directly observed therapy DOT are especially important for patients with HIV-related TB.
- HIV-infected patients are often taking medication, which might interact with anti-TB medications for example rifampicin, which interacts with antiretroviral agents and other anti-infectives, for example fluconazole.

**Table 73.3:** Suggested Timing of HAART in HIV/TB Co-infection

CD4 count cells/ $\mu$ L	When to treat with HAART
<100	As soon as possible; dependent on physician assessment, (Some physicians delay up to 2 months)
100–200	After 2 months of TB treatment
>200	After completing 6 months TB treatment

(BHIVA TB/HIV Guidelines 2005)

- There are overlapping toxicity profiles and drug–drug interactions with some anti-TB and anti-retroviral drugs that further complicate the concurrent use of HAART and TB treatment.
- There are also concerns about the timing of commencement of HAART in relation to the start of TB treatment in the context of preventing the risk of further HIV progression and the occurrence of paradoxical reactions

The optimal time to start HAART in TB/HIV patients is not known (Table 73. 3). Physicians have to balance the risk of HIV progression if HAART is delayed against the risk of having to discontinue therapies because of toxicities, side effects, paradoxical reactions, or unforeseen drug–drug interactions if HAART is started.

Drug–drug interactions between HIV and TB therapy arise through shared routes of metabolism and are often due to enzyme induction or inhibition.<sup>41,42</sup> One important family of enzymes is the hepatic cytochrome P450 (CYP) system. The non-nucleoside reverse transcriptase inhibitors and protease inhibitors have clinically important drug interactions with the rifamycins, as the latter are potent inducers of CYP3A4.

The inducing effect of rifampicin not only takes at least 2 weeks to become maximal but will also persist for at least 2 weeks after rifampicin has been stopped. If antiretrovirals have been started or changed at the end of TB treatment, this persistent effect on enzyme induction should be taken into consideration. In addition, rifampicin increases the activity of the efflux multi-drug transporter P-glycoprotein (P-gp) that contributes to the elimination of protease inhibitors (PIs).

Until more data are available, low-dose ritonavir/PI combinations should not be given with rifampicin-based regimens. In these cases rifampicin should be substituted for rifabutin, or the protease inhibitor and ritonavir switched to an alternative antiretroviral if alternatives exist.

HIV-seropositive TB group showed an annual mortality of 68% despite adequate TB treatment.<sup>43</sup> Multidrug resistant TB (MDR-TB) and XDR-TB have presented a greater challenge to public health. Resistance to multiple drugs emerges due to (i) inadequate treatment doses, (ii) irregular intake of drugs, (iii) incorrect prescription, and (iv) improper monitoring and supervision. XDR-TB is defined as resistance to at least rifampicin and isoniazid among the first-line anti-TB drugs (which is the definition of MDR-TB) in addition to resistance

**Table 73.4:** Recommended Treatment Regimens for Each Diagnostic Category

TB diagnostic category	TB patients	TB treatment regimens	
		Initial phase (daily or 3 times weekly)	Continuation phase (daily or 3 times weekly)
I	New smear-positive patients New smear-negative pulmonary TB with extensive parenchymal involvement. Severe concomitant HIV disease or severe forms of extrapulmonary TB	2HRZE	4HR or 6HE daily
II	Previously treated sputum smear-positive pulmonary TB: • relapse • treatment after default • treatment failure	2 HRZES/1HRZE	5HRE
III	New smear-negative pulmonary TB (other than in Category I). Less severe forms of extrapulmonary TB.	2HRZE	4HR or 6HE daily
IV	Chronic and MDR-TB (still sputum-positive are suggested for this category after supervised [refer to the current WHO] re-treatment)	Especially designed individualized cases or standardized regimens are suggested for this category	

Note: The numerals in the table represent duration of treatment in months.

Abbreviations: H, INH; R, Rifampicin; E, Ethambutol; Z, Pyrazinamide; S, Streptomycin.

Adapted from World Health Organization. *Treatment of Tuberculosis. Guidelines for National Programmes*. 3rd ed. Geneva, Switzerland, 2003. (WHO/CDS/TB/2003.313)

to any fluoroquinolone, and to at least one of three injectable second-line anti-TB drugs used in TB treatment (capreomycin, kanamycin, and amikacin) (Table 73.4, WHO).

India's national TB control program provides care, diagnosis, and treatment on a huge scale.<sup>44,45</sup> Of course, HIV treatment is often more complex and expensive than TB treatment and must continue indefinitely. When patients with HIV infection are treated at the same facility as those with TB, effective infection-control measures are essential, given the high risk of nosocomial transmission of TB. When caring for co-infected patients, physicians must consider many clinical issues, such as those related to the prevention of disease; the timing of treatment; the choice of medications; drug interactions, side effects, and resistance; and potential re-infection with other mycobacterium strains.

### Mycobacterium Avium-Intracellulare (MAC, MAI)

*Mycobacterium avium* and *Mycobacterium intracellulare* are collectively known as the *Mycobacterium avium* complex (MAC). It is transmitted through inhalation, ingestion, or inoculation via the respiratory or gastrointestinal tract. There is no increased risk of transmission to household or close contacts and person-to-person transmission is unlikely.

In the absence of effective ART or chemoprophylaxis in those with AIDS-associated immunosuppression, the incidence of disseminated MAC disease is 20–40%.<sup>46,47</sup> For persons with a CD4+ count less than 100 cells/ $\mu$ L who are receiving effective prophylaxis or have responded to ART with a sustained increase in CD4+ count to levels greater than 100–200 cells/ $\mu$ L, the overall incidence has been estimated at 2 cases per 100 person-years.

MAC disease typically occurs among persons with CD4+ counts less than 50 cells/ $\mu$ L. Other factors that are associated with increased susceptibility to MAC disease are high plasma HIV RNA levels (>100,000 copies/mL), previous OIs, and previous colonization of the respiratory or gastrointestinal tract with MAC.

MAC disease is typically a disseminated multi-organ infection<sup>48–51</sup> in persons with AIDS not on ART. The early symptoms are minimal and might precede detectable mycobacteremia by several weeks. The symptoms include fever, night sweats, weight loss, fatigue, diarrhea, and abdominal pain.<sup>52</sup>

Localized manifestations of MAC disease have been reported most frequently among persons who are receiving and have responded to ART. They include cervical or mesenteric lymphadenitis, pneumonitis, pericarditis, osteomyelitis, skin or soft tissue abscesses, genital ulcers, or CNS infection.

Laboratory abnormalities particularly associated with disseminated MAC disease include anemia (often out of proportion to that expected for the stage of HIV disease) and elevated liver alkaline phosphatase.<sup>53,55,56</sup> Hepatomegaly, splenomegaly, or lymphadenopathy (paratracheal, retroperitoneal, para-aortic, or less commonly peripheral) might be identified on physical examination or by radiographic or other imaging studies. Other focal physical findings or laboratory abnormalities might occur in the context of localized disease.

Recognition of atypical Mycobacterium is important in the treatment of infections in these patients and in the understanding of epidemiology of atypical mycobacterial infections.

Due to non-availability of diagnostic facilities in developing countries MAC is often under-reported.

HIV-infected adults and adolescents should receive chemoprophylaxis against disseminated MAC disease if they have a CD4+ count of less than 50 cells/ $\mu$ L with azithromycin or clarithromycin which can be discontinued in patients who have responded to ART with an increase in CD4+ counts to greater than 100 cells/ $\mu$ L for more than 3 months. Disseminated MAC can be treated with clarithromycin/azithromycin and ethambutol. Some physicians elect to add a third drug from among rifabutin, ciprofloxacin, or amikacin in patients with extensive disease.<sup>54</sup>

## Bacterial Respiratory Disease

Bacterial pneumonia occurs commonly in HIV-infected patients. Risk factors associated with an increased risk for bacterial pneumonia include low CD4+ count, injection-drug use, and cigarette smoking.<sup>57</sup> *Streptococcus pneumoniae* and *Haemophilus* species are the most frequently identified causes of community-acquired bacterial pneumonia in HIV-infected persons.<sup>58–63</sup> *Pseudomonas aeruginosa* and *Staphylococcus aureus* are also reported as community-acquired pathogens with an increased frequency among persons with HIV infection.<sup>61,64</sup> These persons also have an increased incidence of bacteremia accompanying pneumonia, especially if they are infected with *S. pneumoniae*.<sup>65–67</sup> The clinical and radiographic presentation of bacterial pneumonia in HIV-infected persons is similar to that in persons without HIV infection although they might present with multifocal or multilobar involvement and with parapneumonic effusions more frequently than persons without HIV infection.<sup>68</sup>

No effective means exist to reduce exposure to *Streptococcus pneumoniae* and *Haemophilus influenzae*, which are common in the community. HIV-infected adults and adolescents who have a CD4+ count of greater than 200 cells/ $\mu$ L should be administered a single dose of 23-valent polysaccharide pneumococcal vaccine unless they have received this vaccine during the previous 5 years.

The principles of the treatment of community-acquired bacterial pneumonia are the same for HIV-infected persons as for HIV-uninfected persons.<sup>69</sup>

## Bacterial Enteric Infections

HIV infected people have a 20- to 100-fold higher incidence of gram-negative bacterial enteric infections than the general population.<sup>70–74</sup> *Salmonella* (particularly *Salmonella* serotypes Typhimurium and Enteritidis), *Shigella*, and *Campylobacter* are the most common in adults. The probable source for most HIV-infected associated infections is ingestion of contaminated food or water.<sup>72</sup> *E. coli* seems to be the most common offending organism in developing countries but it does not cause an increased morbidity as compared to *Salmonella*, *Shigella*, and *Campylobacter*.

The three major clinical syndromes of infection with gram-negative enteric bacteria in HIV-infected patients include:

- **Self-limited** gastroenteritis.
- A **more severe and prolonged** diarrheal disease, associated with fever, bloody diarrhea, weight loss, and possible bacter-

emia (bloody diarrhea is more frequent with *Shigella* but also can occur with *Campylobacter* or *Salmonella*).<sup>75,76</sup>

- **Septicemia**, which can exhibit extra-intestinal involvement with or without concurrent or preceding gastrointestinal illness.<sup>77–80</sup>

Recurrent *Salmonella* septicemia constitutes an AIDS-defining illness and might require chronic suppressive therapy.<sup>70</sup>

## Bartonellosis

Three *Bartonella* species (*B. bacilliformis*, *B. quintana*, and *B. henselae*) are currently considered important causes of human disease.

The infections caused by *Bartonella* species include cat scratch disease, trench fever, relapsing bacteremia, endocarditis, bacillary angiomatosis (BA), and bacillary peliosis hepatis.<sup>81</sup> The latter two manifestations occur only in immunocompromised persons. BA is caused by either *B. quintana* or *B. henselae*.<sup>81,82</sup> BA most often occurs late in HIV infection, in patients with a median CD4+ count of less than 50 cells/ $\mu$ L.<sup>82</sup> In HIV-infected patients, bartonellosis is often a chronic illness, lasting for months to years, with BA lesions and intermittent bacteremia.

Development of BA lesions caused by *B. henselae* is statistically linked to cat exposure in patients with HIV infection.<sup>82</sup> In contrast, BA caused by *B. quintana* is associated with body louse infestation and homelessness.<sup>82</sup>

BA lesions are seen in nearly every organ system, but cutaneous lesions are the most readily identified. BA lesions can be clinically indistinguishable from Kaposi sarcoma (KS). BA also can cause subcutaneous nodules. Osteomyelitis is usually caused by *B. quintana*, and only *B. henselae* can cause bacillary peliosis hepatis. Although isolated organs can appear to be the principal focus of disease, BA represents a hematogenously disseminated infection, and systemic symptoms of fever, night sweats, and weight loss often accompany BA. *Bartonella* infection is a major cause of unexplained fever in late-stage AIDS patients and should be considered in the differential diagnosis of patients with fever and a CD4+ count of less than 100 cells/ $\mu$ L.<sup>83</sup>

Diagnosis can be confirmed by histopathologic examination of biopsied tissue.<sup>84</sup> PCR methods have been developed for identification and speciation of *Bartonella*, but are not widely available. This disease, again like MAC infection, is under reported from developing countries owing to lack of diagnostic facilities.

## FUNGAL

### Pneumocystis Pneumonia

*Pneumocystis pneumonia* (PCP) is caused by *Pneumocystis jiroveci*, a ubiquitous organism that is classified as a fungus but that also shares biological characteristics with protozoa. *Pneumocystis carinii* now refers only to the pneumocystis that infects rodents, and *Pneumocystis jiroveci* refers to the distinct species that infects humans. Initial infection with *P. jiroveci* usually occurs in early childhood; two-thirds of healthy children have antibodies to

*P. jiroveci* by age 2–4 years.<sup>85</sup> Approximately 90% of cases occurred among patients with CD4+ counts of less than 200 cells/ $\mu$ L before the use of ART. The other factors associated with a higher risk for PCP included CD4+ cell percentage <14%, previous episodes of PCP, oral thrush, recurrent bacterial pneumonia, unintentional weight loss, and higher plasma HIV RNA.<sup>86,87</sup>

With the widespread use of ART the incidence of PCP has decreased considerably. The majority of cases occur among patients who are unaware of their HIV infection or are not receiving ongoing HIV care<sup>88</sup> or among those with advanced immunosuppression (CD4+ count <100 cells/ $\mu$ L).<sup>89</sup>

Subacute onset of progressive dyspnea, fever, non-productive cough, and chest discomfort that worsens within days to weeks are the most common manifestations of PCP. In mild cases, pulmonary examination is usually normal at rest. With exertion, tachypnea, tachycardia, and diffuse dry ('cellophane') rales might be observed.<sup>90</sup> Oral thrush is a common co-infection. Fever is apparent in the majority of cases and might be the predominant symptom among some patients. Extrapulmonary disease is rare but can occur in any organ and has been associated with use of aerosolized pentamidine prophylaxis.

Hypoxemia is the most characteristic laboratory abnormality. Oxygen desaturation with exercise is indicative of an abnormal alveolar arterial oxygen partial pressure gradient ( $[A-a]O_2$ ) but is non-specific.<sup>91</sup> The chest radiograph typically demonstrates diffuse, bilateral, and symmetrical interstitial infiltrates emanating from the hila in a butterfly pattern; however, patients with early disease might have a normal chest radiograph.<sup>92</sup> Pneumothorax in a patient with HIV infection should raise the suspicion of PCP.<sup>93,94</sup>

High-resolution computerized tomography (CT) demonstrates patchy ground-glass shadows. A definitive diagnosis requires histopathologic demonstration of organisms in tissue, bronchoalveolar lavage fluid, or induced sputum samples,<sup>93,94</sup> as the other common findings are not pathognomonic for PCP. Spontaneously expectorated sputum has low sensitivity and should not be submitted to the laboratory to diagnose PCP.

HIV-infected adults and adolescents, including pregnant women and those on ART, should receive chemoprophylaxis against PCP if they have a CD4+ count of less than 200 cells/ $\mu$ L or a history of oropharyngeal candidiasis.<sup>86,95,96</sup> Persons who have a CD4+ cell percentage of less than 14% or a history of an AIDS-defining illness, but do not otherwise qualify, should be considered for prophylaxis.<sup>86,95,96</sup> When monitoring CD4+ counts frequently (e.g., every 1–3 months) is not possible, initiating chemoprophylaxis at a CD4+ count of greater than 200 cells/ $\mu$ L, but less than 250 cells/ $\mu$ L, should also be considered.<sup>95</sup>

Trimethoprim/sulfamethoxazole (TMP-SMX) is recommended for prophylaxis.<sup>96</sup> One double-strength tablet daily is the preferred regimen. However, one single-strength tablet daily<sup>97</sup> is also effective and might be better tolerated than one double-strength tablet daily. One double-strength tablet three times weekly is also effective.<sup>98</sup> TMP-SMX at a dose of one double-strength tablet daily confers cross-protection against toxoplasmosis and selected common respiratory bacterial infection.

Alternative prophylactic regimens include dapsone, dapsone plus pyrimethamine plus leucovorin, aerosolized pentamidine administered by the Respigard II nebulizer, and atovaquone. Primary pneumocystis prophylaxis should be discontinued for adult and adolescent patients who have responded to ART with an increase in CD4+ counts to greater than 200 cells/ $\mu$ L for more than 3 months. Prophylaxis should be reintroduced if the CD4+ count decreases to less than 200 cells/ $\mu$ L.

TMP-SMX is also the treatment of choice for acute PCP.<sup>99,100</sup> The dose must be adjusted for abnormal renal function. Usual dose is (TMP) 20 mg/kg/day, (SMX) 75–100 mg/kg/day in divided tid/qid. Alternative therapeutic regimens for mild-to-moderate disease include the following:

- (i) Dapsone and TMP
- (ii) Primaquine plus clindamycin
- (iii) Atovaquone suspension. Patients should be tested for **Glucose-6-phosphate dehydrogenase** deficiency whenever possible before administration of primaquine.

Alternative therapeutic regimens for patients with moderate-to-severe disease include clindamycin-primaquine or intravenous (IV) pentamidine<sup>101–103</sup> (usually the drug of second choice for severe disease). Aerosolized pentamidine should not be used for the treatment of PCP because of limited efficacy and more frequent relapse.<sup>102,104,105</sup> The recommended duration of therapy for PCP is 21 days.

## Mucocutaneous Candidiasis

*Candida albicans* causes majority of infections. *C. glabrata* is a cause of refractory mucosal candidiasis in patients with advanced immunosuppression. Extensive, recurrent candidial infection of the gastrointestinal tract, lungs, and skin is observed among severely immunosuppressed individuals.<sup>106–109</sup> A study conducted in Mumbai, India, reported 54% of oral candidiasis among individuals with HIV disease were caused by *Candida tropicalis*.<sup>110</sup>

Patients with CD4+ counts less than 200 cells/ $\mu$ L often present with oropharyngeal or esophageal candidiasis. This is recognized as an indicator of immune suppression.<sup>111</sup> In contrast, vulvovaginal candidiasis is common among healthy, adult women and is unrelated to HIV status.

Oropharyngeal candidiasis is characterized by painless, creamy white, plaque-like lesions of the buccal or oropharyngeal mucosa or tongue surface. Lesions can be easily scraped off with a tongue depressor or other instrument. Less commonly, erythematous patches without white plaques can be seen on the anterior or posterior upper palate or diffusely on the tongue. Angular cheilitis is also noted on occasion and might be caused by *Candida*.

Esophageal candidiasis is occasionally asymptomatic but retrosternal burning pain or discomfort and odynophagia are often present. Endoscopic examination is needed to confirm the diagnosis.

Candida vulvovaginitis is similar to that in normal hosts, and is characterized by a white adherent vaginal discharge associated with mucosal burning and itching. In those with advanced

immunosuppression, episodes might be more severe and more frequently recurrent. Compared with oropharyngeal candidiasis, vaginal candidiasis is less frequent and rarely refractory to azole therapy.

Routine primary prophylaxis is not recommended because mucosal disease is associated with very low attributable mortality, acute therapy is highly effective, prophylaxis can lead to disease caused by drug-resistant species, prophylactic agents can produce drug interactions, and prophylaxis is expensive. ART does reduce the likelihood of mucosal candidiasis.

Oral fluconazole is as effective and may be superior to topical therapy for oropharyngeal candidiasis. Initial episodes of oropharyngeal candidiasis can be adequately treated with topical therapy, including clotrimazole troches and nystatin suspension.<sup>112</sup>

Vulvovaginal candidiasis in HIV-infected women is usually uncomplicated (90%) and responds readily to short-course oral or topical treatment with either of the following:

- Oral fluconazole
- Topical azoles (clotrimazole, miconazole)
- Oral itraconazole

Severe or recurrent episodes of vaginitis require oral fluconazole or topical antifungal therapy for 7 days or more.

## Cryptococcus Neoformans

*Cryptococcus neoformans* is a common OI reported in patients with AIDS in Asia and the Pacific.<sup>106,108,113,114</sup> The majority of HIV-associated cryptococcal infections are caused by *Cryptococcus neoformans* and observed among patients who have CD4+ counts of less than 50 cells/ $\mu$ L.

Cryptococcosis most commonly occurs as a subacute meningitis or meningoencephalitis with fever, malaise, and headache among patients with HIV infection.<sup>115</sup> When cryptococcosis occurs in the HIV-infected patient, disseminated disease is common. Skin lesions mimicking molluscum contagiosum are frequently observed. In addition, isolated pulmonary infection is evident; symptoms and signs include cough and dyspnea in association with an abnormal chest radiograph.

The diagnosis of cryptococcal meningitis is made by identification of organisms in spinal fluid with India ink examination or by the detection of cryptococcal antigen. The serum cryptococcal antigen is also almost always positive in cases of CNS disease and in other instances of disseminated infection. As such, testing for serum cryptococcal antigen is a useful initial screening tool in diagnosing cryptococcosis in HIV-infected patients.<sup>116</sup> Up to 75% of patients with HIV-associated cryptococcal meningitis have routine blood cultures positive for *C. neoformans*.

The recommended initial standard treatment is amphotericin B deoxycholate, at a dose of 0.7 mg/kg daily, combined with flucytosine, at a dose of 100 mg/kg daily in four divided doses, for 2 weeks or more for those with normal renal function. Renal

function should be monitored closely and the flucytosine dose adjusted appropriately for patients with renal impairment.

## Penicillium Marneffeii

Penicilliosis marneffeii (penicilliosis) is caused by the dimorphic fungus *Penicillium marneffeii*, which is endemic in Southeast Asia (especially Northern Thailand) and southern China.<sup>117–119</sup> More recently, 50 indigenous cases of penicilliosis occurred in Manipur, India, identified as a new endemic area of this fungus.<sup>120,121</sup> It is considered an AIDS-defining condition in those parts of the world where it occurs. *P. marneffeii* is the third most common AIDS-defining illness in Thailand, following TB and cryptococcosis. The majority of cases of penicilliosis are observed in patients who have CD4+ counts of less than 100 cells/ $\mu$ L.<sup>122</sup>

Very little was known about the epidemiology and natural reservoir of *P. marneffeii* except that its occurrence increased during the rainy season.<sup>123</sup> Skin lesions, usually papules with central necrotic umbilication, provide the most significant clue to the diagnosis. Cutaneous penicilliosis lesions commonly appear on the face, ears, extremities, and occasionally the genitals.

Disseminated infection presents clinically with generalized lymphadenopathy (90%), hepatomegaly (90%), fever greater than 38.5°C (81%), papular skin lesions with central umbilication (67%), splenomegaly (67%), failure to thrive in children (52%), severe anaemia (43%), and thrombocytopenia (21%).<sup>124</sup> Involvement of other organs such as bone marrow, lymph nodes, lung, liver, and intestine have been reported.

Early diagnosis based on finding *P. marneffeii* in the skin smear or lymph node provides the basis for prompt administration of antifungal therapy.<sup>124</sup> The definitive diagnosis of penicilliosis is based on isolation of organisms from blood culture or other clinical specimens or by histopathologic demonstration of organisms in biopsy material. Many intracellular and extracellular basophilic, spherical, oval, and elliptical yeast-like organisms can be seen, some with clear central septation, which is a characteristic feature of *P. marneffeii*.<sup>125</sup>

*P. marneffeii* is highly susceptible to miconazole, itraconazole, ketoconazole, and 5-flucytosine. Amphotericin B has intermediate antifungal activity, whereas fluconazole is the least active.<sup>126</sup> The recommended treatment is amphotericin B in a dose of 0.6 mg/kg body weight/day administered intravenously for 2 weeks, followed by oral itraconazole in a dose of 400 mg/day for a subsequent duration of 10 weeks. Patients with mild disease can be initially treated with oral itraconazole 400 mg/day for 8 weeks,<sup>127</sup> followed by 200 mg/day for prevention of recurrence. ART should be administered in accordance with standards of care in the community; consideration should be given to simultaneous administration of treatment for penicilliosis and initiation of ART to improve outcome. A study from Chiang Mai University documented that approximately 50% of patients had relapse of

penicilliosis within 6 months after discontinuation of antifungal therapy.<sup>127,128</sup> A double-blind, placebo-controlled study from Chiang Mai, Thailand, demonstrated that oral itraconazole 200 mg daily for secondary prophylaxis in AIDS patients reduced the relapse rate of *Penicilliosis marneffei* from 57% to 0% ( $P < 0.001$ ). All patients who successfully complete treatment for penicilliosis should be administered secondary prophylaxis (chronic maintenance therapy) with oral itraconazole in a dose of 200 mg/day.

Discontinuing secondary prophylaxis for penicilliosis is recommended for AIDS patients who receive combination ART and have CD4+ count greater than 100 cells/ $\mu$ L for 6 months or more. Secondary prophylaxis should be reintroduced if the CD4+ count decreases to less than 100 cells/ $\mu$ L or if penicilliosis recurs at a CD4+ count of greater than 100 cells/ $\mu$ L.

## Aspergillosis

Invasive aspergillosis in the HIV-infected persons is rare. It is most frequently caused by *Aspergillus fumigatus*, although certain cases are caused by *A. flavus*, *A. niger*, and *A. terreus*. Neutropenia, use of corticosteroids, exposure to broad-spectrum antibacterial therapy, and previous pneumonia or other underlying lung disease are specific risk factors. Patients who have had HIV-associated aspergillosis typically have CD4+ count less than 100 cells/ $\mu$ L, a history of other AIDS-defining OIs, and are not receiving ART.

Invasive aspergillosis in the HIV-infected patient is evidenced most commonly as a respiratory illness that can be a necrotizing pneumonia or a tracheobronchitis.<sup>129</sup> Symptoms of invasive pneumonia are fever, cough, dyspnea, chest pain, hemoptysis, and hypoxemia; the chest radiograph might demonstrate a diffuse, focal, or cavitory infiltrate. A “halo” of low attenuation surrounding a pulmonary nodule or an “air-crescent” on CT scan of the lung is suggestive of disease. Extrapulmonary forms of invasive aspergillosis include sinusitis, cutaneous disease, osteomyelitis, and CNS infection.<sup>130</sup>

The diagnosis of pulmonary aspergillosis is usually based on either (i) the repeated isolation of *Aspergillus* spp. from cultures or respiratory secretions or (ii) the finding of dichotomously branching septate hyphae consistent with *Aspergillus* spp. in respiratory or other samples in association with a compatible clinical syndrome. Newer tests based on circulating fungal antigen have been employed to diagnose aspergillosis. A sandwich ELISA test for galactomannan, a major fungal cell wall antigen, can be used on serum and bronchoalveolar lavage fluid.<sup>131</sup>

The recommended treatment for invasive aspergillosis in patients without HIV infection is voriconazole<sup>132</sup> but should be used cautiously with HIV PIs and efavirenz. Amphotericin B deoxycholate at 1 mg/kg daily or lipid-formulation amphotericin B at 5 mg/kg daily are alternatives, as is caspofungin at 50 mg daily and posaconazole. The length of therapy is not established but should continue at least until the peripheral blood CD4+ count is greater than 200 cells/ $\mu$ L and there is evidence of clinical response.

## VIRAL (INCLUDING OPPORTUNISTIC CANCERS)

### Herpes Simplex

Herpes simplex causes primary, secondary, or recurrent genital and extragenital, including oral, lesions. In individuals with severe immunosuppression, recurrent herpes is frequent, likely to be painful, and slow to heal. Orolabial herpes is the most common manifestation of HSV-1 infection. Genital herpes is the most common manifestation of HSV-2 infection. In profoundly immunocompromised patients, extensive, deep, and non-healing genital ulcerations might occur. These lesions have been reported most often in those with CD4+ count of less than 100 cells/ $\mu$ L and also might be more commonly associated with acyclovir-resistant virus.<sup>133</sup> The episodes of genital HSV-1 infection are indistinguishable from genital HSV-2 infection but genital HSV-1 infection recurs less frequently than genital HSV-2 infection.

Non-mucosal HSV infections, such as HSV keratitis, HSV encephalitis, HSV hepatitis, and herpetic whitlow, are similar in presentation to those manifestations observed in HIV-seronegative persons; disseminated HSV infection is rare.

A laboratory diagnosis should be pursued in all cases where possible because mucosal lesions are not diagnosed accurately. PCR is the most sensitive method, but is not widely available. Diagnosis of HSV-2 should be accompanied by counseling that discusses the risk for transmission of infection to sex partners.

Patients with HSV infections can be treated with episodic therapy when lesions occur or with daily therapy to prevent recurrences. Treatment for individual recurrences does not influence the natural history of genital HSV-2 infection and does not reduce the risk for HSV-2 transmission to sex partners, a major concern of persons with genital herpes.

Patients with orolabial lesions can be treated with oral valacyclovir, famciclovir, or acyclovir for 5–10 days. Severe mucocutaneous HSV lesions respond best to initial treatment with IV acyclovir.<sup>133,134</sup> Patients may be switched to oral therapy after the lesions have begun to regress. Therapy should be continued until the lesions have completely healed. Genital HSV infection should be treated with oral valacyclovir, famciclovir, or acyclovir for 5–14 days.

### Varicella Zoster Virus

A person's lifetime risk for herpes zoster is 15–20%, with the highest incidence occurring in the elderly and immunocompromised persons. The incidence of herpes zoster is more than 15-fold higher for HIV-infected adults than for age-matched controls.<sup>135</sup> Herpes zoster can occur in HIV-infected adults at any CD4+ count, but frequency of disease is highest with CD4+ count of less than 200 cells/ $\mu$ L and is not reduced by ART.<sup>136–138</sup>

Herpes zoster manifests as a painful cutaneous eruption in a dermatomal distribution, often preceded by prodromal pain. The most common sites for herpes zoster are the thoracic dermatomes (40–50% of cases), followed by cranial nerve (20–25%), cervical (15–20%), lumbar (15%), and sacral (5%) dermatomes. The

probability of a recurrence of herpes zoster within 1 year of the index episode is approximately 10%.<sup>138,139</sup> Approximately 10–15% of HIV-seropositive patients report post-herpetic neuralgia as a complication following herpes zoster.<sup>140</sup> Most herpes zoster-related complications, including herpes zoster dissemination, occur in patients with CD4+ count of less than 200 cells/ $\mu$ L.<sup>140</sup> The CNS is the primary target organ for herpes zoster dissemination in patients coinfecting with HIV. Various VZV-related neurologic syndromes occur in HIV-infected patients, including CNS vasculitis, multifocal leukoencephalitis, ventriculitis, myelitis and myeloradiculitis, optic neuritis, cranial nerve palsies and focal brain-stem lesions, and aseptic meningitis.

Varicella and herpes zoster are distinctive in appearance and can usually be diagnosed clinically. Varicella can be diagnosed retrospectively by documenting seroconversion. When lesions are atypical or the diagnosis is uncertain, swabs from a fresh lesion or tissue biopsies can be submitted for viral culture, direct fluorescent antigen testing, or PCR, provided facilities are available.

For uncomplicated varicella, recommended treatment options are oral acyclovir (20 mg/kg body weight up to a maximum dose of 800 mg five times daily), valacyclovir (1 g PO tid), or famciclovir (500 mg PO tid) for 5–7 days. IV acyclovir for 7–10 days (10 mg/kg every 8 hours for 10–14 days) is the recommended initial treatment for HIV-infected patients with severe chickenpox. Prompt antiviral therapy should be instituted in all immunosuppressed herpes zoster patients within 1 week of rash onset or any time before full crusting of lesions. The recommended treatment options for acute localized dermatomal herpes zoster in HIV-infected patients are oral valacyclovir, famciclovir, or acyclovir for 7–10 days.

## Cytomegalovirus Disease

Most clinical disease occurs in previously infected (seropositive) persons and so represent either reactivation of latent infection or reinfection with a novel strain.

End-organ disease caused by CMV occurs among persons with advanced immunosuppression, typically those with CD4+ count less than 50 cells/ $\mu$ L, who are either not receiving or have failed to respond to ART.<sup>141–143</sup> Other risk factors include previous OIs and high plasma HIV RNA levels (>100,000 copies/mL). The incidence of new cases of CMV end-organ disease has declined by 75–80% with the advent of ART.

Retinitis is the most common clinical manifestation of CMV end-organ disease. CMV retinitis occurs as unilateral disease in two-thirds of patients at presentation, but in the absence of therapy or immune recovery, viremic dissemination results in bilateral disease in the majority of patients.<sup>144</sup> For patients with unilateral CMV retinitis and CD4+ count less than 50 cells/ $\mu$ L, rates of contralateral disease approach those of the pre-ART era.<sup>145</sup> CMV retinitis is a full-thickness necrotizing retinitis, and the characteristic ophthalmologic appearance is that of fluffy yellow-white retinal lesions, with or without intraretinal hemorrhage, and with little inflammation of the vitreous unless immune recovery with potent ART intervenes.<sup>141</sup>

Colitis occurs in a small proportion of persons with AIDS and CMV end-organ disease. The most frequent clinical manifestations are fever, weight loss, anorexia, abdominal pain, debilitating diarrhea, and malaise. Extensive mucosal hemorrhage and perforation can be life-threatening complications.

Esophagitis caused by CMV, which occurs in less than 5–10% of persons with AIDS who experience CMV end-organ disease, causes fever, odynophagia, nausea, and occasionally mid-epigastric or retrosternal discomfort. CMV pneumonitis is uncommon. CMV neurologic disease causes dementia, ventriculoencephalitis, or ascending polyradiculomyelopathy.<sup>145</sup> Cerebrospinal fluid (CSF) typically demonstrates lymphocytic pleocytosis (although a mixture of neutrophils and lymphocytes might be evident), low-to-normal glucose levels, and normal-to-elevated protein levels. CMV polyradiculomyelopathy causes a Guillain-Barre-like syndrome characterized by urinary retention and progressive bilateral leg weakness. The clinical symptoms usually progress during several weeks to include loss of bowel and bladder control and to flaccid paraplegia.

CMV viremia can be detected by PCR or antigen assays and is usually observed in end-organ disease, but viremia also might be present in the absence of end-organ disease.<sup>145–150</sup> The presence of serum antibodies to CMV is not diagnostically useful, although a negative IgG antibody level indicates that CMV is unlikely to be the cause of the disease process. The diagnosis of CMV retinitis is usually made based on recognition of characteristic retinal changes observed through a dilated pupil during an ophthalmoscopic examination performed by an experienced ophthalmologist. The diagnosis of CMV esophagitis is established by the presence of extensive large, shallow ulcers of the distal esophagus and biopsy evidence of intranuclear inclusion bodies in the endothelial cells with an inflammatory reaction at the edge of the ulcer.<sup>142</sup>

Oral valganciclovir, IV ganciclovir, IV ganciclovir followed by oral valganciclovir, IV foscarnet, IV cidofovir, and the ganciclovir intraocular implant coupled with valganciclovir are all effective treatments for CMV retinitis. Because ART can control CMV retinitis without anti-CMV therapy in patients who experience immune recovery, some clinicians might consider not treating small peripheral CMV lesions with anti-CMV therapy in ART-naïve patients. IV ganciclovir or foscarnet (or with oral valganciclovir if symptoms are not severe enough to interfere with oral absorption) for 21–28 days form the mainstay of treatment for other CMV infections.

## Oral Hairy Leukoplakia and Epstein–Barr Virus

Oral hairy leukoplakia (OHL) presents as striated white lesions on the lateral margins of the tongue (Table. 73.7), and less frequently on buccal and genital mucosa. It occurs in about 20% of those with asymptomatic HIV infection and becomes more common as the CD4+ count falls.<sup>151</sup>

Diagnosis of OHL is a clinical indicator of rapid disease progression. A study at the University of California showed that 26% of individuals developed oral candidiasis and 42%

developed OHL within 5 years after seroconversion.<sup>152</sup> Another longitudinal study in the US showed that 47% and 67% of individuals developed AIDS within 2 and 4 years of occurrence of OHL, respectively.<sup>153</sup> OHL has been attributed to Epstein-Barr virus (EBV).<sup>154</sup> Several studies in Asia and the Pacific have also reported OHL.<sup>109</sup>

### Non-Hodgkin Lymphoma: Malignancy With Viral Etiology

High-grade B cell non-Hodgkin lymphoma (NHL) is an increasingly important condition in individuals infected with HIV (Table. 73.8).<sup>109,155</sup> It is associated with relatively poor prognosis for survival.<sup>155</sup> CNS NHL occurs more frequently when CD4+ count fall below 50 cells/ $\mu$ L. NHL is possibly due to viral antigenic-mitogenic stimulation leading to cytokine-mediated B cell overproliferation and/or emergence of EBV-infected and immortalized B cells. Fifty percent of these tumors harbour the EBV with a reported equal frequency of EBV A and B subtypes in the tumors.<sup>156</sup>

### Kaposi Sarcoma

Human herpes virus type 8 (HHV-8) is associated with all forms of Kaposi Sarcoma (KS) (i.e., classic, endemic, transplant-related, and AIDS-related) and certain rare neoplastic (e.g., primary effusion lymphoma) and lymphoproliferative disorders (multicentric Castleman disease). The seroprevalence is greater among MSM (20–77%). The precise pathogenesis is unclear even though seroconversion to HHV-8 precedes the development of these tumors.<sup>157</sup>

Malawi, a KS endemic area reports a high titer of HHV-8 in HIV-seropositive men as compared to the HIV-seropositive women.<sup>158</sup> In Asia and the Pacific, where HIV is predominantly transmitted heterosexually, fewer cases of KS have been reported. In decreasing order of frequency, KS is reported in men, women, and children.<sup>155,159–161</sup> Lymph node, oral, gastrointestinal, respiratory, hepatic, and cerebral involvement are reported from the Asia-Pacific region.

Most persons with chronic HHV-8 infection are asymptomatic.<sup>162</sup> Acquisition of HHV-8 has been associated with a primary infection syndrome consisting of fever, rash, lymphadenopathy, bone marrow failure, and occasional rapid progression to KS.<sup>163,164</sup> KS symptoms vary widely, but most persons have non-tender, purplish, indurated skin lesions. Intraoral lesions are common and visceral dissemination can occur, occasionally without the presence of skin lesions.

The introduction of ART since 1995 has reduced the incidence of KS and NHL precipitously.<sup>165</sup> Definitive treatment guidelines do not exist for established KS. Fewer than 10% of AIDS patients with KS die as a consequence of their malignancy, and death from secondary infections is considerably more common. Treatment should be reserved for lesions causing significant discomfort or cosmetic problems. The options are localized

radiation, intralesional vinblastine, or cryotherapy.<sup>166</sup> Systemic therapy with interferon alpha or chemotherapy can be tried for multiple or visceral lesions. Liposomal daunorubicin, liposomal doxorubicin, and paclitaxel are the agents tried.<sup>166–168</sup>

### Progressive Multifocal Leukoencephalopathy

Progressive multifocal leukoencephalopathy (PML) is an OI of the CNS, caused by the polyoma virus JC virus (JCV) and characterized by focal demyelination.<sup>169</sup> The virus has worldwide distribution and approximately 85% of adults are seropositive for JCV.<sup>170</sup> Before the advent of potent combination ART, PML eventually occurred in 3–7% of AIDS patients<sup>171,172</sup> but has substantially decreased with the advent of HAART.

PML manifests as focal neurological deficits, usually with insidious onset and steady progression. The MRI almost always confirms distinct white matter lesions in areas of the brain corresponding to the clinical deficits. In contrast to cerebral toxoplasmosis and primary CNS lymphoma, no mass effect or displacement of normal structures is usually evident. JCV DNA by PCR is positive in 70–90% of the cases not taking ART. No established specific therapy exists for JCV infection or PML, and the main approach to treatment involves ART to reverse the immunosuppression that interferes with the normal host response to this virus.

## PROTOZOAL

### Toxoplasmosis

Toxoplasmic encephalitis (TE) is caused by the protozoan *Toxoplasma gondii*. The disease appears to occur almost exclusively because of reactivation of latent tissue cysts.<sup>173–176</sup> Primary infection occasionally is associated with acute cerebral or disseminated disease.

Clinical disease is rare among patients with CD4+ count greater than 200 cells/ $\mu$ L. The greatest risk occurs among patients with a CD4+ count less than 50 cells/ $\mu$ L.<sup>173–175,177</sup> Primary infection occurs after eating undercooked meat containing tissue cysts or ingesting oocysts that have been shed in cat feces and have sporulated in the environment (sporulation requires at least 24 hours). No transmission of the organism occurs by person-to-person contact.

The most common clinical presentation of *T. gondii* infection among patients with AIDS is focal encephalitis with headache, confusion, motor weakness, and fever.<sup>173–175</sup> Physical examination might demonstrate focal neurological abnormalities, and in the absence of treatment, disease progression results in seizures, stupor, and coma. Retinochoroiditis, pneumonia, and evidence of other multifocal organ system involvement can be observed after dissemination of infection but are rare manifestations in this patient population. CT scan or MRI of the brain will typically show multiple contrast-enhancing lesions, often with associated edema.<sup>173,174,178–180</sup> However, toxoplasmosis also can manifest as single lesions in the brain.

HIV-infected patients with TE are almost uniformly seropositive for anti-toxoplasma immunoglobulin G (IgG) antibodies.<sup>173,174</sup> The absence of IgG antibody makes a diagnosis of toxoplasmosis unlikely but not impossible. Anti-toxoplasma immunoglobulin M (IgM) antibodies are usually absent. Quantitative antibody titers are not diagnostically useful. Definitive diagnosis of TE requires a compatible clinical syndrome; identification of one or more mass lesions by CT, MRI, or other radiographic testing; and detection of the organism in a clinical sample. This requires a brain biopsy, which is most commonly performed by a stereotactic CT-guided needle biopsy.

The differential diagnosis of focal neurological disease in patients with AIDS includes CNS lymphoma, mycobacterial infection (especially TB), fungal infection (e.g., cryptococcosis), Chagas disease, bacterial abscess, and rarely PML, which can be distinguished on the basis of imaging studies (PML lesions typically involve white matter rather than gray matter, are non-contrast enhancing, and produce no mass effect).

HIV-infected persons should be tested for IgG antibody to *Toxoplasma* soon after the diagnosis of HIV infection to detect latent infection with *T. gondii*. To minimize risk for acquiring toxoplasmosis, HIV-infected persons should be advised not to eat raw or undercooked meat, including undercooked lamb, beef, and pork. HIV-infected persons should wash their hands after contact with raw meat and after gardening or other contact with soil; in addition, they should wash fruits and vegetables well before eating them raw. If the patient owns a cat, the litter box should be changed daily, preferably by an HIV-negative, non-pregnant person.

*Toxoplasma*-seropositive patients who have a CD4+ count of less than 100 cells/ $\mu$ L should be administered prophylaxis against TE.<sup>181</sup> Prophylaxis against TE should be discontinued among adult and adolescent patients who have responded to ART with an increase in CD4+ count to greater than 200 cells/ $\mu$ L for more than 3 months.

The initial therapy of choice for TE consists of the combination of pyrimethamine plus sulfadiazine plus leucovorin.<sup>182–185</sup> Pyrimethamine penetrates the brain parenchyma efficiently even in the absence of inflammation.<sup>186</sup> Use of leucovorin reduces the likelihood of the hematologic toxicities associated with pyrimethamine therapy.<sup>187,188</sup>

The preferred alternative regimen for patients with TE who are unable to tolerate or who fail to respond to first-line therapy is pyrimethamine plus clindamycin plus leucovorin.

## Cryptosporidiosis

Cryptosporidiosis is caused by various species of the protozoan parasite *Cryptosporidium*, which infect the small bowel mucosa, and in immunosuppressed persons, the large bowel and extra-intestinal sites. Persons at greatest risk for disease have advanced immunosuppression, typically CD4+ count of less than 100 cells/ $\mu$ L.<sup>189</sup> The three most common species infecting humans are *C. hominis*, *C. parvum*, and *C. meleagridis*. Infection occurs through ingestion of *Cryptosporidium* oocysts. Chronic diarrhea

due to *C. parvum* is reported in 20 to 25% of patients with AIDS in India.<sup>190–192</sup>

Patients with cryptosporidiosis most commonly have acute or subacute onset of profuse, non-bloody, watery diarrhea, accompanied often by nausea, vomiting, and lower abdominal cramping.<sup>193</sup> Fever is present in approximately one-third of patients and malabsorption is common. The epithelium of the biliary tract and the pancreatic duct can be infected with *Cryptosporidium*, leading to sclerosing cholangitis and to pancreatitis secondary to papillary stenosis, particularly among patients with prolonged disease and low CD4+ counts.<sup>194–197</sup>

Diagnosis of cryptosporidiosis can be made by microscopic identification of the oocysts in stool or tissue. *Cryptosporidium* oocysts also can be detected by direct immunofluorescence, which offers the greatest sensitivity and specificity, or by enzyme-linked immunosorbent assay (ELISA).<sup>198</sup>

Scrupulous handwashing can reduce the risk for diarrhea in HIV-infected persons, including diarrhea caused by *Cryptosporidium*.<sup>199</sup> Water should be boiled before drinking as the most simple measure.

In the setting of severe immunosuppression, ART with immune restoration to a CD4+ count greater than 100 cells/ $\mu$ L leads to resolution of clinical cryptosporidiosis.<sup>200</sup> and is the mainstay of treatment. Therefore, patients with cryptosporidiosis should be offered ART as part of the initial management of their infection. Multiple agents have been investigated in small, randomized controlled clinical trials on HIV-infected adults, including nitazoxanide, paromomycin, spiramycin, bovine hyperimmune colostrum, and bovine dialyzable leukocyte extract.

## Microsporidium

Microsporidia are related to fungi, defined by the presence of a unique invasive organelle consisting of a single polar tube that coils around the interior of the spore.<sup>201,202</sup> In the immunosuppressed host, clinical signs related to microsporidiosis are most commonly observed when the CD4+ count is less than 100 cells/ $\mu$ L.<sup>201–203</sup> The most common manifestation of microsporidiosis is gastrointestinal tract infection with diarrhea; however, encephalitis, ocular infection, sinusitis, myositis, and disseminated infection also are described.<sup>201,203</sup> Effective morphologic demonstration of microsporidia by light microscopy can be accomplished by staining methods that produce differential contrast between the spores of the microsporidia and the cells and debris in clinical samples (e.g., stool). In biopsy specimens, microsporidia can be visualized with Giemsa, tissue Gram stains (Brown–Hopps Gram stain), calcofluor white or Uvitex 2B (fluorescent brighteners) staining, Warthin–Starry silver staining, hematoxylin and eosin, or Chromotrope 2A.<sup>204</sup>

Patients with AIDS (e.g., CD4+ count less than 200 cells/ $\mu$ L) should avoid untreated water sources. Otherwise, other than general attention to handwashing and other personal hygiene measures, no precautions to reduce exposure to microsporidia are recommended.

ART with immune restoration (an increase of CD4<sup>+</sup> count to > 100 cells/ $\mu$ L) is associated with resolution of symptoms of enteric microsporidiosis, including that caused by *E. bieneusi*.<sup>200,205–207</sup>

## Leishmaniasis

Leishmaniasis is caused by obligate intracellular protozoa that survive and replicate in intracellular vacuoles within macrophages. The *Leishmania* genus has traditionally been differentiated into multiple species that cause cutaneous, mucosal, or visceral disease.<sup>208,209</sup> Leishmaniasis among persons with HIV/AIDS has been reported primarily from Spain, Italy, France, Brazil, and Ethiopia, but most coinfections in the developing world are never reported.<sup>210</sup> The incidence has decreased substantially in developed countries with the introduction of ART<sup>211,212</sup>; however, HIV-leishmaniasis coinfection poses a growing problem in Asia and Africa.<sup>213,214</sup>

After primary infection, *Leishmania* remain viable in healthy persons for long periods, leading to a susceptible population if immunosuppression occurs. In HIV-infected persons without severe immunosuppression, disease manifestations are similar to those in immunocompetent persons. Among those with advanced immunosuppression and low CD4<sup>+</sup> counts (<200 cells/ $\mu$ L), manifestations of leishmaniasis might be both atypical and more severe, and relapse after treatment is common.<sup>215</sup>

The most common clinical presentation of leishmaniasis in persons with AIDS is a disseminated visceral disease syndrome, but the distribution varies geographically, reflecting differences in the predominant parasite species. Among persons with visceral disease, the most common clinical and laboratory findings are fever (65–100%), systemic malaise (70–90%), splenomegaly (usually moderate, 60–90%), hepatomegaly without splenomegaly (34–85%), hepatosplenomegaly (68–73%), lymphadenopathy (12–57%), and pancytopenia (50–80%). Anemia is usually marked with less than 10 g hemoglobin/dL (49–100%), leukopenia moderate with less than 2400 leukocytes/ $\mu$ L (56–95%), and thrombocytopenia is usually present (52–93%). Splenomegaly is somewhat less common in HIV-coinfected patients than in immunocompetent patients with visceral leishmaniasis.<sup>216</sup>

Demonstration of characteristic amastigote forms of *Leishmania* by histopathology, cultures, and smears in tissue specimens (e.g., scrapings, aspirates, and biopsies) is the standard for diagnosis of cutaneous leishmaniasis among HIV-coinfected patients.<sup>217</sup> The diagnosis of visceral leishmaniasis can also be made by the demonstration of amastigote forms in cultures from the peripheral blood, and smears or cultures from bone marrow or splenic aspirates. Other methods useful for demonstrating *Leishmania* in the blood or tissue of coinfecting patients include detection of *Leishmania* nucleic acid by PCR amplification (>95% sensitivity).<sup>218</sup>

Antibodies against *Leishmania* antigens are of high sensitivity for the diagnostic value among immunocompetent patients with visceral disease.<sup>219</sup> However, the sensitivity of serologic tests is substantially lower in HIV-coinfected patients.<sup>220</sup> The use of

recombinant antigen (e.g., rK39) in ELISA assays might increase sensitivity, but a proportion of coinfecting patients will remain seronegative.<sup>221</sup>

For HIV-visceral leishmaniasis-coinfecting patients, the efficacy of conventional and lipid-associated formulations of amphotericin B appears to be similar to that of pentavalent antimony. However, liposomal and lipid complex preparations are substantially better tolerated than conventional amphotericin B or pentavalent antimony.<sup>222–224</sup>

## Management Of Opportunistic Infections: General Principles to Consider

Clinicians treating HIV-infected patients often have to consider two questions related to OIs and ART:

- (i) When to initiate ART in ART-naïve persons who experience an acute OI.
- (ii) How ART should be managed for persons who are on ART but who experience an acute OI.

Initiation of ART has been documented to be effective for OIs for which effective therapy does not exist for example, cryptosporidiosis, microsporidiosis, and PML.<sup>225–227</sup> For KS, initiation of ART has been documented to lead to resolution of lesions in the absence of specific therapy for the sarcoma.<sup>228</sup> It also has preventive benefit—a second OI is less likely to occur if ART is started promptly rather than delaying the initiation of ART.

The disadvantages of starting ART in a setting of OI are many. There may be failure to absorb the ART drugs leading to subtherapeutic serum levels and development of antiretroviral drug resistance. ART toxicities might be confused with disease manifestations or toxicities associated with drugs used for treating patients with an OI. Drug–drug interactions among ART and anti-OI drugs might be difficult to manage. Renal or hepatic dysfunction during acute OIs might make dosing of ART drugs difficult to estimate. Finally, IRIS (see below) events can occur and cause manifestations that are difficult to distinguish from other clinical conditions.

For these reasons, no consensus has been reached concerning the optimal time to start ART in the setting of a recently diagnosed OI. However, one recently completed randomized clinical trial has demonstrated a clinical and survival benefit of starting ART early, within the first 2 weeks, of initiation of treatment for an acute OI, excluding TB.<sup>229</sup>

OIs that occur after patients have been started on ART can be categorized into three groups. The first group includes OIs that occur shortly after initiating ART (within 12 weeks). These cases might be subclinical infections that have been unmasked by early immune reconstitution or simply OIs that occurred because of advanced immunosuppression and are not considered to represent early failure of ART. Many of these cases represent IRIS.<sup>230–235</sup>

The second group includes OIs that occur more than 12 weeks after initiation of ART among patients with suppressed

**Table 73.5:** Recommendations for Minimizing Exposure to Selected Pathogens among Patients with HIV Infection

Pathogen	Potentially effective intervention
<i>Pneumocystis jiroveci</i>	Avoid close contact with patients who have active <i>P. carinii</i> pneumonia (e.g., avoid sharing hospital room)
<i>Toxoplasma gondii</i>	Avoid eating undercooked red meat and exposure to cats that scavenge for food outdoors
<i>Cryptosporidium</i>	Avoid drinking unprocessed ground water (e.g., from lakes or streams); use properly boiled, bottled, or filtered water; avoid household pets less than 6 months of age, especially those that were obtained from commercial breeders or pet shelters, that were previously strays, or that have diarrhea; emphasize good hygiene in child care
<i>Mycobacterium tuberculosis</i>	Avoid high-risk occupational settings, such as correctional facilities, homeless shelters, and certain healthcare situations
CMV	If patient is seronegative for CMV, avoid transfusion with CMV-seropositive or unfiltered blood products; avoid unprotected sexual exposure. Emphasize good hygiene in child care
Human papillomavirus, herpes simplex virus, and Hepatitis B	Avoid unprotected sexual exposure Immunisation

HIV RNA levels and sustained CD4+ count greater than 200 cells/ $\mu$ L.<sup>236,237</sup> Determining whether these represent a form of IRIS rather than incomplete immunity with the occurrence of a new OI is difficult. The third group includes OIs that occur among patients who are experiencing virologic and immunologic failure while on ART. These represent clinical failure of ART.

When an OI occurs within 12 weeks of starting ART, treatment for the OI should be started and ART should be continued. When an OI occurs despite complete virologic suppression (i.e., late OI),

therapy for the OI should be initiated and ART should be continued. If the CD4+ response to ART has been suboptimal, modification of the ART regimen may be considered, although no evidence exists to indicate that changing the ART regimen in this setting will improve the CD4+ response. When an OI occurs in the setting of virologic failure, OI therapy should be started, antiretroviral resistance testing should be performed, and the ART regimen should be modified, if possible, to achieve better virologic control.

Tables 73.5, 73.6, 73.7, and 73.8 summarize the management of OIs in HIV patients (Adapted from Kovacs JA, Masur H. Prophylaxis against opportunistic infections in patients with human immunodeficiency virus infection. *NEJM* 2000;342:1416–29).

### Immune Reconstitution Inflammatory Syndrome (IRIS)

IRIS consists of several distinct disorders that appear to result from dysfunction of those aspects of immune reconstitution that affect restoration of pathogen-specific immune responses and/or immune regulation.<sup>238</sup>

It is the paradoxical deterioration in clinical status after ART initiation despite improved immune function. It typically occurs in patients with low initial CD4 (usually <50) and a rapid decline in viral load. The usual onset is within 6 weeks of ART initiation, but sometimes several months later.<sup>239–241</sup>

Immune reconstitution is usually seen with infections with *M. avium* complex, *M. tuberculosis* (30% of cases), and other mycobacteria, CMV, *Cryptococcus*, PCP, Leishmania, HSV, VZV, Hepatitis B & C, JC virus, HHV 8, and others.

It can present with fever, localized lymphadenopathy/lymphadenitis, abscesses, pneumonia, vitritis, CNS disease, hepatitis, and dermatologic manifestations. Presentations of OIs may be atypical.

MAC: Granulomatous lymphadenopathy without mycobacteremia.

CMV: Vitritis.

PML: enhancing CNS lesions.

*Cryptococcosis*: marked CSF leukocytosis.

**Table 73.6:** Drug Regimens for Primary Prophylaxis against OIs in Patients with HIV Infection

Pathogen	First choice	Alternatives
<i>Pneumocystis jiroveci</i>	Trimethoprim–sulfamethoxazole, 1 double strength tablet orally per day or 1 single strength tablet orally per day	Trimethoprim–sulfamethoxazole, 1 double-strength tablet orally 3 times a week; Dapsone, 50 mg orally twice a day or 100 mg orally per day; Dapsone, 50 mg orally per day, plus pyrimethamine, 50 mg orally once a week, plus leucovorin, 25 mg orally once a week; Dapsone, 200 mg orally once a week, plus pyrimethamine, 75 mg orally once a week, plus leucovorin, 25 mg orally once a week; Atovaquone, 1500 mg orally per day; Aerosolized pentamidine, 300 mg monthly by Respigard II nebulizer
<i>Toxoplasma gondii</i>	Trimethoprim–sulfamethoxazole, 1 double-strength tablet orally per day	Trimethoprim–sulfamethoxazole, 1 single-strength tablet orally per day; Dapsone, 50 mg orally per day, plus pyrimethamine, 50 mg orally once a week, plus leucovorin, 25 mg orally once a week; Atovaquone, 1500 mg orally per day
<i>M. avium</i> complex	Azithromycin, 1200 mg orally once a week; or Clarithromycin, 500 mg orally twice a day	Rifabutin, 300 mg orally per day; Azithromycin, 1200 mg orally once a week, plus rifabutin, 300 mg orally per day

**Table 73.7:** Drug Regimens for Secondary Prophylaxis against OIs after Chemotherapy for Acute Infection in Patients with HIV Infection

Pathogen	First choice	Alternatives
<i>Pneumocystis jiroveci</i>	Trimethoprim–sulfamethoxazole -1 double strength tablet orally per day or 1 single strength tablet orally per day	Same as primary
<i>Toxoplasma gondii</i>	Sulfadiazine, 500–1000 mg orally 4 times a day, plus pyrimethamine, 25–75 mg orally per day, plus leucovorin, 10 mg orally per day	Clindamycin, 300 mg orally 4 times a day or 450 mg orally 3 times a day, plus pyrimethamine, 25–75 mg orally per day, plus leucovorin, 10–25 mg orally per day
<i>Mycobacterium avium</i> complex	Clarithromycin, 500 mg orally twice a day, plus ethambutol, 15 mg/kg of body weight orally per day, with or without rifabutin, 300 mg orally per day	Azithromycin, 500 mg orally per day, plus ethambutol, 15 mg/kg orally per day, with or without rifabutin, 300 mg orally per day
CMV	Ganciclovir, 5–6 mg/kg intravenously 5–7 days a week or 1000 mg orally 3 times a day; Valganciclovir 900 mg bid PO Foscarnet, 90–120 mg/kg intravenously per day; (for retinitis) ganciclovir sustained-release implant, every 6–9 mo, plus ganciclovir, 1000 to 1500 mg orally 3 times a day	Cidofovir 5 mg/kg every other week IV + Probenecid Fomivirsen 330 mg intravitreal q2–4 wk Valganciclovir 900 mg PO daily
<i>Cryptococcus neoformans</i>	Fluconazole, 200 mg orally per day	Itraconazole 200 mg/d PO
Salmonella species (not <i>S. typhi</i> ) bacteremia	Ciprofloxacin, 500 mg orally twice a day for 6–8 months	None
Herpes simplex virus	None; if recurrences are severe or frequent, consider acyclovir, 200 mg orally 3 times a day or 400 mg orally twice a day	Famciclovir, 500 mg orally twice a day; Valacyclovir, 500 mg orally twice a day
Candida oropharyngeal, oesophageal, or vaginal)	None; if recurrences are severe or frequent, consider fluconazole, 100–200 mg orally per day	Itraconazole, 200 mg orally per day
<i>Penicillium marneffei</i>	Itraconazole 200 mg/d PO	-

**Table 73.8:** Recommendation for Initiating and Discontinuing Primary and Secondary Prophylaxis for Adults and Adolescents with HIV Infection

Pathogen	Primary prophylaxis			Secondary prophylaxis		
	Start	Stop	Restart	Start	Stop	Restart
<i>Pneumocystis jiroveci</i>	CD4 cell count <200/ $\mu\text{m}^3$ or oropharyngeal candidiasis	CD4 cell count >200/ $\mu\text{m}^3$ for 3–6 mo	Same as to start	Prior <i>P. jiroveci</i> pneumonia	CD4 cell count >200/ $\mu\text{m}^3$ for 3–6 mo	Same as for primary prophylaxis
<i>Toxoplasma gondii</i>	CD4 cell count <100/ $\mu\text{m}^3$ and IgG antibodies to toxoplasma	Follow <i>P. jiroveci</i> pneumonia guidelines, since all agents other than aerosol pentamidine will have some activity	Follow <i>P. jiroveci</i> pneumonia guidelines	Prior toxoplasmosis	Lifelong*	NA
<i>M. avium</i> complex	CD4 cell count <50/ $\mu\text{m}^3$	CD4 cell count >100/ $\mu\text{m}^3$ for 3–6 mo	Same as to start	Prior <i>M. avium</i> complex disease	Lifelong*	NA
CMV	Not recommended	NA	NA	Prior CMV disease	CD4 cell count >100–150/ $\mu\text{m}^3$ for 3–6 mo; non-sight-threatening lesion, adequate vision in other eye, and regular eye examination	CD4 cell count <50/ $\mu\text{m}^3$
Herpes simplex virus, varicella–zoster virus, candida species, <i>Cryptococcus neoformans</i> , <i>Histoplasma capsulatum</i> , <i>Coccidioides immitis</i>	Not recommended	NA	NA	Recommended only for prior cryptococcal, histoplasma, or coccidioides disease	Lifelong for cryptococcal, histoplasma, or coccidioides disease*	NA

\*The data available are not sufficient to stop secondary prophylaxis.

Autoimmune diseases may be exacerbated. In active TB although there is a high risk of paradoxical worsening after initiation of ART, the overall mortality is improved in coinfecting patients with CD4 greater than or equal to 100/ $\mu$ L treated with ART.<sup>242,243</sup>

Diagnosis of IRIS is clinically challenging and involves differentiation from progression of the initial OI (including the possibility of antimicrobial resistance and treatment failure), development of a new OI, unrelated organ dysfunction, or drug toxicity.

Therapy for IRIS has been empiric. No well-controlled trials exist to help decide when non-steroidal drugs or corticosteroids are needed or when ART should be suspended. The inflammation might take weeks or months to subside. IRIS does not appear to have favorable or unfavorable implications about patient survival, with the possible exception of IRIS associated with cryptococcal meningitis.<sup>240,244</sup>

The general principles include the following:

- Treating the underlying active infection
- Continue ART, unless inflammatory response is life threatening
- Anti-inflammatory therapy (NSAIDs and/or corticosteroids)
- Response to corticosteroids typically rapid. Slow taper may be required
- Initiation of ART during the treatment of active OIs is controversial. Timing of ART depends on severity of OI and degree of immunosuppression.

## SPECIFIC MEASURES

**MAC (Lymphadenitis):** NSAIDs initially; if symptoms persist steroids may be indicated. Surgical drainage may be needed for abscesses.

**M. tuberculosis:** Steroids for 2 weeks with slow taper. TB should be treated for more than 2 months before HAART unless CD4 less than 100.

**CMV vitritis:** Systemic or periocular steroids.

**Hepatitis:** HBV co-infection consider using Tenofovir with Lamivudine or Emtricitabine.

**Cryptococcal meningitis:** Steroids and serial LPs to manage elevated CSF pressure.

## Conclusion

In Asia and the Pacific region, fewer clinicians are willing to provide care and support to persons living with HIV/AIDS. The laboratory infrastructure required for identification of OIs is grossly inadequate. Hence, most published reports present frequency of syndromes such as chronic diarrhoea, weight loss greater than 10% of body weight, recurrent fever, chronic cough, persistent headache, and cutaneous manifestations caused by a host of OIs. It is up to the clinicians to reach a

diagnosis with the available limited resources, unlike in the developed countries and this is what makes it more challenging as well as interesting.

## Mucocutaneous Manifestations of HIV

Yogesh Marfatia • Ranjan Rawal  
• Keyur Shah • Smriti Naswa

### Introduction

The skin, being the most visible and largest organ, often shows early manifestations of internal disease; same holds true for human immunodeficiency virus (HIV) disease. Skin is the most commonly affected organ in patients with HIV/AIDS with more than 90% of HIV-infected patients developing cutaneous signs and symptoms. Cutaneous manifestations can occur through all stages of HIV infection. Dermatological diseases in HIV are a spectrum of inflammatory, infectious, and oncogenic disorders. They are in most of the situations diagnostic markers of HIV infection and opportunistic infections. Severe opportunistic infections may present for the first time in the skin.<sup>1</sup> They have specific prognostic significance independent of other markers, and are more helpful in situations where facilities for CD4 count and viral load are not easily available to monitor the progression of the disease.

Dermatological manifestations may also be cosmetically disfiguring and source of severe morbidity, both physical and psychological. The skin lesions in seropositive patients may be atypical and response to treatment may be poor. In addition, the HIV epidemic has brought to attention previously rare and poorly understood skin diseases, such as bacillary angiomatosis, Kaposi sarcoma, and eosinophilic folliculitis.

Mucocutaneous disorders of HIV should thus be considered among key clinical indicators for prediction of underlying immune status as well as immune reconstitution inflammatory syndrome (IRIS).

There is a tremendous change observed in the mucocutaneous manifestations in pre-ART and post-ART era. In the pre-ART era, numerous and varied opportunistic infections, malignancies and DNA viral infections were common. Most cutaneous manifestations of HIV infection clear spontaneously with ART. In the ART era, mucocutaneous manifestations have been replaced by antiretroviral therapy (ART)-related adverse drug reactions (ADR) and endocrinal and metabolic changes. Dermatologists should be well-grounded in the diagnosis and treatment of these conditions.<sup>2</sup>

### Skin and HIV Interaction

The skin-specific immune surveillance system includes antigen-presenting Langerhans cells, dermal and epidermal T lymphocytes, cytokine-producing keratinocytes, and draining peripheral lymph nodes. In the HIV-1 infected, this surveillance system appears to be compromised, as evidenced by a reduction in the epidermal Langerhans cell population. Because human epidermal Langerhans cell expresses surface-bound CD4 antigens, HLA-DR antigens, and Fc-IgG receptors, all of which are involved in HIV-1 binding to, or entry into, the target cell; the reduction in Langerhans cells in patients with acquired immunodeficiency syndrome (AIDS) may be a direct consequence of HIV-1 infection and consequent injury to Langerhans cells leading to decreased Langerhans cell function.<sup>3</sup>

Preputial skin contains lot of Langerhans cells. These cells are the prime targets for HIV. Impairment of skin immune system is responsible for mucocutaneous manifestations even before the development of complete immunodeficiency.

### Classification

As stated previously, mucocutaneous manifestations occur during all stages of HIV infection and they can be inflammatory, infectious, oncogenic or non-specific in nature. A brief classification of the various mucocutaneous manifestations is given; there can be a combination of any of the inflammatory or infectious disorders and in a given patient, more than one infectious agent may be responsible for the final clinical picture.

#### A. Infectious manifestations

1. Viral infections
  - (a) Acute exanthema of HIV
  - (b) Herpes simplex virus (HSV)/varicella zoster virus (VZV)
  - (c) Epstein-Barr virus (EBV)/cytomegalovirus (CMV)
  - (d) Human papillomavirus (HPV)
  - (e) Molluscum contagiosum

- (f) Others: Hepatitis B/C, human T-cell lymphotropic virus (HTLV)
- 2. Bacterial infections
  - (a) *Staphylococcus aureus*
  - (b) Mycobacterial infection
  - (c) Bacillary angiomatosis
- 3. Fungal infections
  - (a) Dermatophytosis
  - (b) Candidiasis
  - (c) Other superficial mycoses—*Malassezia furfur*, Trichosporosis
  - (d) Deep and systemic mycoses—Cryptococcosis, histoplasmosis, penicilliosis
- 4. Parasitic infections
  - (a) Arthropod infections—Scabies and demodicidosis
  - (b) Protozoal infections—Pneumocystosis, toxoplasmosis, leishmaniasis

## B. Non-infectious dermatoses

- 1. Papulosquamous disorders
  - (a) Ichthyosiform dermatitis—dryness, eczema
  - (b) Seborrheic dermatitis
  - (c) Psoriasis
  - (d) Reiter disease
- 2. Pruritic eruptions of HIV
  - (a) Follicular
    - (i) Eosinophilic folliculitis
    - (ii) Demodex folliculitis
    - (iii) Pityrosporum folliculitis
  - (b) Non-follicular
    - (i) Papular
    - (ii) Eczematous
  - (c) Papular pruritic eruptions (PPE)
  - (d) Others—Pruritus in HIV
- 3. Pigmentary disorders
- 4. Cutaneous adverse drug reactions (ADR)
- 5. Neoplasms—Kaposi sarcoma, lymphoma
- 6. Miscellaneous—Pityriasis rubra pilaris (PRP), immune thrombocytopenic purpura (ITP), pityriasis rosea (PR), photosensitivity

## C. Cutaneous adverse drug reactions (ADR) of ART

### D. Specific mucosal manifestations

- 1. Gingivitis/periodontitis
  - (a) Linear gingival erythema
  - (b) Necrotizing ulcerative periodontitis
- 2. Angular cheilitis
- 3. Necrotizing stomatitis
- 4. Autoimmune/idiopathic
  - (a) Recurrent aphthae
  - (b) Immune thrombocytopenic purpura (ITP)
  - (c) Salivary gland disease

- (d) Abnormal pigmentation
- 5. Tuberculosis
- 6. Viral
  - (a) Oral hairy leukoplakia (OHL)
  - (b) Herpes simplex virus (HSV)
  - (c) Herpes zoster virus (HZV)
  - (d) Human papillomavirus (HPV)
- 7. Fungal
  - Oral candidiasis
- 8. Malignancy
  - (a) Kaposi sarcoma (KS)
  - (b) Non-Hodgkin lymphoma (NHL)

### E. Hair manifestations

- 1. Premature graying of hair
- 2. Diffuse hair loss
- 3. Male pattern alopecia
- 4. Alopecia areata
- 5. Long eyelashes

### F. Nail manifestations

- 1. Onychomycosis
- 2. Yellowish discoloration
- 3. Melanotic bands
- 4. Black pigmentation—due to zidovudine (AZT)

## VIRAL INFECTIONS

### Acute Exanthem of HIV Seroconversion Illness

Acute exanthem accompanied by HIV seroconversion refers to an acute viral prodrome with cutaneous eruptions. Acute primary HIV infection/seroconversion may go unnoticed, unreported or undiagnosed. It usually lasts for a few days. There is a symmetrical maculopapular erythematous exanthem of face, palms, and soles found in 75% of the persons with symptomatic seroconversion.<sup>4</sup> It may occasionally manifest as exanthem, urticaria, toxic erythema, erythema multiforme (EM), oropharyngeal candidiasis, acute genitocrural intertrigo, and oral or genital ulcerations. More severe and numerous the manifestations, and more prolonged the duration; more likely is the rapid progression of HIV disease.

### Herpes Simplex Virus

Herpes simplex viral infection is one of the most common opportunistic infections in the HIV-infected patients. It can be symptomatic or an asymptomatic carrier state. HIV type 1 (HIV-1)-infected persons have high rates of HSV type 2 (HSV-2) infection, ranging from 50% to 90% in studies of HIV-infected populations from different parts of the world.<sup>5</sup> HIV and HSV are co-transmitters of each other. There is 3–4 fold rise in plasma HIV load during acute outbreaks of HSV infection and there is two-fold increased risk of HIV acquisition in patients having genital herpes due to mucosal barrier disruption and presence of activated T lymphocytes

**Fig. 74.1:** Giant genital herpes.

in the ulcer base.<sup>6</sup> HIV-positive patients with HSV infection shed more herpes simplex virus from genital mucosal tract even in the absence of clinical herpes.

Presence of chronic herpetic ulcers of longer than 1 month duration is an AIDS defining condition. Tender, often painful ulcerative lesions of genital region, perianal area and lip are the hallmark of HSV in HIV-infected patients (Fig. 74.1). Anogenital erosions may progress to chronic, crusted, vegetative or ulcerative lesions. HSV reactivation occurs significantly more often and most of these reactivations are perirectal and subclinical. As the immunodeficiency progresses, HSV infection becomes chronic, persistent, progressive and recurrent, responding less promptly to oral antiviral therapy.

Loss of nail due to herpetic infection may occur. HSV can cause persistent necrotic digits—"herpetic whitlow" (Fig. 74.2 a&b) and perioral ulceration, which may spread to oropharynx, oesophagus, and cause odynophagia. Follicular facial lesions have also been reported. In a study of 200 HIV-positive cases Marfatia et al.<sup>6</sup> reported cryptic herpes presenting as herpetic esophagitis in 0.5% and herpetic cervicitis in 1% cases. Secondary bacterial infection is almost always seen. Concomitant infection with CMV in the form of hyperkeratotic verrucous lesions has been observed. Serious clinical complications of HSV in the presence of HIV are dissemination, encephalitis, and development of acyclovir resistance.

Diagnosis of herpes requires high index of suspicion, particularly in atypical presentation and subclinical reactivation. Tzanck smear and biopsy for acantholytic cells and multinucleate giant cells are performed to confirm the diagnosis. Viral culture or polymerase chain reaction (PCR) needs to be performed for a definitive diagnosis. Electron microscopy of fresh lesional fluid, DNA hybridization, immunofluorescence, and sera for HSV antibodies can be examined to support the diagnosis.<sup>4</sup>

HSV and HIV co-infection is often referred to as double trouble. Thereby, aggressive treatment of herpetic ulcers is of vital importance in HIV management. Early administration of 200 mg acyclovir five times a day is known to suppress HSV2 reactivation (Fig. 74.3

\*c+

\*d+

**Fig. 74.2:** Herpetic Whitlow; (a) pre-acyclovir treatment, (b) post-acyclovir treatment.

a&b) and there is a good rationale for using acyclovir suppressive therapy to prevent HIV transmission.<sup>6</sup> Vidarabine, famciclovir, and valaciclovir are newer alternatives. Intravenous foscarnet is given for acyclovir-resistant HSV. Cidofovir gel and 5% imiquimod have been effective topical therapies for cutaneous herpetic infections, especially caused by acyclovir-resistant HSV strains.<sup>7,8</sup>

### Varicella Zoster Virus

Herpes zoster is seen in 6.9–25% of Indian population with HIV infection.<sup>9</sup> Occurrence of HZ due to reactivation of the virus is common in HIV patients and may be the first sign of immunosuppression. Since it is rare in normal children, HZ in young children should alert the physician to the possibility of HIV infection.

While in majority of the cases, the disease runs a typical course with a vesicular eruption in a dermatomal pattern, some cases develop severe hemorrhagic and necrotic lesions that may extend over several dermatomes, and eventually disseminate all over the body.<sup>10</sup> According to Leibovitz et al.,<sup>11</sup> chronic VZV infections associated with HIV-1 infection begin as vesicles and progress into necrotic, non-healing ulcers.

Disseminated herpes zoster is defined as involvement of more than three contiguous dermatomes, more than 20 lesions scattered outside the initial dermatome, or presence of systemic infection (hepatitis, pneumonitis, encephalitis).<sup>8</sup> Conjunctivitis or optic

(a)

(b)

**Fig. 74.3:** Giant herpes ulcer in a bed ridden patient; (a) pre-acyclovir treatment, (b) post-acyclovir treatment.

neuritis may complicate herpes zoster ophthalmicus, and patient should be referred to the ophthalmologist. Acute retention of urine, hemorrhagic cystitis, and constipation can occur due to involvement of sacral nerves.

Clinical diagnosis is supported by Tzanck smear and skin biopsy in cases with unusual presentations. Fluorescent antibody testing, viral culture, and PCR are done for confirmation of diagnosis.

Oral acyclovir 800 mg five times a day for 10 days is the treatment of choice.<sup>12</sup> It should be started preferably within 48–72 hours after the appearance of rash. However, in immunocompromised status, they may be treated even after 3 days of onset of the rash. Systemic parenteral therapy with acyclovir 10 mg/kg three times a day for 7–10 days is indicated especially when sight, sphincter function and facial expression are threatened, and where pulmonary or neurological involvement is suspected.<sup>13</sup> Vidarabine, intravenous foscarnet and recombinant IFN- $\alpha$  are possible alternatives for emerging acyclovir resistance.<sup>13</sup> Live attenuated (Oka/Merck Strain) VZV (Zoster Vaccine) may boost immunity and varicella immunoglobulins can prevent or modify the clinical illness.<sup>14</sup> An important component of management is the treatment of pain. Carbamazepine, amitriptyline, and

gabapentin are the options available. Intractable post-herpetic neuralgia has been occasionally treated with intrathecal administration of methyl prednisolone. A topical or systemic antibiotic is often needed for secondary infections.

### Epstein–Barr Virus

Oral hairy leukoplakia (OHL) is caused by the Epstein–Barr virus (EBV). It is considered as one of the first opportunistic infections occurring in approximately 15–20% of HIV-positive individuals.<sup>15</sup> Following the widespread use of highly active antiretroviral therapy in the mid 1990s in western countries, the prevalence of oral hairy leukoplakia has significantly declined. Patients with OHL generally have moderate to advanced immune suppression, with a median CD4 count of approximately 235 cells/ $\mu$ L.<sup>15</sup>

OHL has clear prognostic value for subsequent development of AIDS and it is classified as a CDC category B clinical marker of HIV disease. Typical OHL lesions are asymptomatic, raised, white, non-removable, corrugated hyperkeratotic lesions on oral mucosal surface. The lesions most often cluster on the lateral aspect of the tongue. The lesions can be unilateral or bilateral. OHL can look like thrush, another common problem characterized by white patches that occurs in HIV-positive patients. However, thrush usually comes off when it is lightly scraped with a toothbrush, whereas OHL does not.<sup>16</sup>

In most circumstances, the diagnosis of OHL is made on clinical findings. If a biopsy is performed, histologic features consist of nuclear changes (Cowdry type A inclusions, ground glass appearance, nuclear beading), profound acanthosis, lack of an inflammatory infiltrate, enlarged cells, regions of ballooning cells, and epithelial hyperplasia.

Fortunately, OHL does not usually require specific therapy.<sup>17</sup> Most patients experience resolution of OHL after taking potent antiretroviral therapy.

### Cytomegalovirus (CMV)

Reactivation of CMV in HIV infection occurs with a CD4 count below 50/ $\mu$ L. Skin involvement with CMV is relatively uncommon but when CMV affects the skin, the mortality is about 85% in 6 months.<sup>18</sup>

Ulcers in the perineal region are the most common presentation. HSV is proposed to be the initiating infection leading to ulcer formation, with CMV secondarily localizing in the granulation tissue. Non-specific maculopapular eruptions or papulovesicular, nodular, purpuric, and ulcerative lesions are observed. Diagnosing CMV infection in individuals infected with HIV is considered a poor prognostic sign.

Skin biopsy shows characteristic CMV inclusions and the material can be cultured with human fibroblasts to demonstrate the cytopathic effect.

Treatment and prophylaxis is based on immune reconstitution with ART, although severe cutaneous ulcerative eruptions have been reported after initiation of ART. Intravenous foscarnet, ganciclovir, and cidofovir are specific treatments for severe cases.

## Human Papillomavirus Infection (HPV)

HPV infection is common during the course of HIV disease. HIV-positive women with severe immunosuppression are five times more likely than the HIV-negative women to have lower genital tract neoplasia.<sup>19</sup> Symptomatic HPV infection is only tip of the iceberg. Asymptomatic shedding is much more common in women with HIV/AIDS. Incidence of HPV infection does not decrease with ART and restoration of immune function.<sup>8</sup>

Warts are seen in about 5–30% of patients with HIV.<sup>20</sup> The warts can be extensive, numerous, and resistant to therapy. HPV-5 can cause a pattern similar to epidermodysplasia verruciformis with extensive verruca plana and pityriasis versicolor like warts.<sup>8</sup> Precancerous lesions like squamous cell carcinoma *in situ* (SCCIS) can occur periungually. These tumors are aggressive and erode underlying periosteum and bone.

Anogenital warts (Condyloma acuminata): HPV-6 and HPV-11 are the most frequently found types in anogenital warts and HPV-16 and HPV-18 are associated with carcinoma *in situ* and high-grade dysplasia (Fig. 74.4).<sup>21</sup> HPV causes various grades of squamous intraepithelial lesion (SIL), and invasive squamous cell carcinoma over cervix, anus, perineum, vulva, penis, oropharynx, and nail, more commonly in HIV infected than in HIV non-infected individuals. Invasive cervical cancer is aggressive in nature and is an AIDS defining condition.<sup>22</sup> ART and restoration of immune function may not cause regression of these dysplasias.

Each and every HIV-positive woman should be screened with Pap smear, histopathology, and PCR because asymptomatic shedders carry high potential for spreading the virus. All HIV-infected individuals should be examined annually for HPV infections by direct examination with speculum and anoscope. Samples for Pap smear should be taken during examination and biopsy is performed on individuals with high-grade squamous intraepithelial lesion.

**Fig. 74.4:** Giant genital wart.

Periodic follow-up examination should be done in patients with external anogenital SIL. Extensive intraoral condylomata acuminata (buccal florid papillomatosis) presents as multiple large plaques that can transform to verrucous carcinoma.

Conventional treatment for common warts may fail. Topical imiquimod and cidofovir can be used and HAART can lead to decrease in size of warts. Anal in situ neoplasia (AIN) can be treated with topical imiquimod, podophyllotoxin, 80% trichloroacetic acid or liquid nitrogen. Minimal invasive squamous cell carcinoma (SCC) can be excised and invasive SCC is treated by radiotherapy and chemotherapy. Oral HPV can be treated successfully with 1–3% cidofovir solution.<sup>8</sup>

GARDASIL is a recombinant quadrivalent vaccine against HPV types 6, 11, 16, and 18 which are responsible for 70% of cervical cancers and 90% of genital warts. It is currently indicated for use in girls and young women 9 through 26 years of age, before initiation of sexual activity, for the prevention of cervical, vulval, and vaginal cancers and warts. In July 2009, WHO has approved another cervical cancer vaccine Cervarix. It protects against HPV 16 and 18. Cervarix is formulated with AS04, a proprietary adjuvant that boosts the immune system response to HPV strains for a longer period of time. Due to high cost, HPV vaccination in developing countries seems to be a distant dream.<sup>23</sup>

## Molluscum Contagiosum Virus (MCV)

The molluscum contagiosum is a DNA virus in the Poxviridae family. Before the advent of ART, MCV infections were detected in 10% of individuals with HIV disease and in 30% of those with CD4 counts less than 100 cells/ $\mu$ L.<sup>8</sup> The clinical course of molluscum contagiosum in the HIV-infected patients differs significantly from that in the normal host as immunodeficiency progresses. Characteristic lesions are umbilicated pearly white papules with one or more central dull hyperkeratotic pores. Among HIV-infected individuals, the lesions tend to be numerous and may be nodular (giant molluscum) and disfiguring and the lesions may be of unusual morphology and sizes (Fig. 74.5 a&b).<sup>24</sup> Such unusual forms include solitary, endophytic, aggregated, inflamed, and giant MCs. MCs mimicking sebaceous nevus of Jadassohn, ecthyma, and giant condylomata acuminata have been reported. Widespread lesions are common and highly characteristic of HIV disease, and must be differentiated from cryptococcal histoplasmosis and *Penicillium marneffei* cutaneous lesions.<sup>10</sup> Skin biopsy may be required.

Introduction of ART is very effective for treatment in addition to conventional methods like cryotherapy, electrodesiccation, gentle curettage, and topical tretinoin.<sup>24</sup> For resistant cases, topical imiquimod 5% and topical or intravenous cidofovir can be used.<sup>8</sup>

## Human T-cell Lymphotropic Virus Infections (HTLV)

In HIV-infected adults, an increased incidence of inflammatory dermatoses, including seborrheic dermatitis, psoriasis, and

\*c+

\*d+

**Fig. 74.5:** Molluscum contagiosum: (a) genital, (b) extra genital.

prurigo, has been reported after infection with HTLV-1.<sup>8</sup>

### Hepatitis B (HBV) and Hepatitis C Viruses (HCV)

Hepatitis B (HBV) and HIV co-infection occurs commonly. The incidence of HBV infection was 16.9% among HIV-positive persons and 14.4% among control subjects ( $p < 0.46$ ). The prevalence of HCV seropositivity was 12.7% among HIV-positive persons and 10.0% among control subjects ( $p < 0.31$ ).<sup>5</sup> Infection with HIV not only increases the risk that a person will progress from acute infection

to chronic HBV infection, but can also accelerate the progression of liver disease, resulting in increased morbidity and mortality.

### Other Viral Infections

Parvovirus B19 can cause cutaneous vasculitis and a persistent papular-purpuric gloves and socks syndrome with anemia.<sup>4</sup>

### BACTERIAL INFECTIONS

*Staphylococcus aureus* is the most common bacterial pathogen causing cutaneous and systemic infections in HIV disease. High prevalence of skin diseases due to *S. aureus* may be explained by high nasal carriage rates for the organism ( $\geq 50\%$ ) and altered immune function in conjunction with an impaired cutaneous barrier.<sup>25</sup> Up to 83% of patients with AIDS suffer from *S. aureus* infection at some point during the course of the disease and it is more commonly seen in HIV-infected children.<sup>26</sup> Drug using behavior and high-risk sex are the common risk factors for skin and soft tissue infections with *S. aureus*.<sup>8</sup> The incidence of infection increases with increasing immunosuppression. Bullous impetigo, ecthyma, staphylococcal scalded skin syndrome (SSSS), folliculitis, furuncles, carbuncles, cellulitis, hidradenitis-like lesions, botryomycosis, and pyomyositis constitute the wide range of primary staphylococcal infections in HIV. Secondary infection occurs in atopic dermatitis, herpetic ulcers, Kaposi sarcoma, scabies, and intertrigo. The most common mode for hematogenous dissemination is intravenous catheter.<sup>8</sup> Diagnosis is established by culture from appropriate sites. Management is directed at the acute infection and treatment of underlying dermatoses. Methicillin-resistant *S. aureus* may pose problems. Recurrent infection can be prevented by eradication of nasal carriage of *S. aureus* with mupirocin ointment (bid for 5 days each month) and long-term prophylaxis with rifampicin.

*Pseudomonas aeruginosa* causes primary infection like ecthyma gangrenosum and panniculitis in advanced HIV disease.

**Bacillary angiomatosis (BA)** is the vascular proliferative response to infection with gram negative, cat scratch disease organism, *Bartonella henselae* and *Bartonella quintana*. It most commonly affects skin and subcutaneous tissue. It usually occurs in patients with CD4 count  $< 200/\mu\text{L}$ . A major challenge in diagnosis of cutaneous BA is diverse presentation of the lesions. Cutaneous lesions may take one of the following forms: (i) solitary or multiple red, purple, flesh-colored hemangioma-like papules; (ii) nodules, often covered with a fine tightly adherent scale, mainly seen in subcutaneous variety; (iii) large, friable, pedunculated or polypoid exophytic masses; or (iv) hyperpigmented, hyperkeratotic, indurated plaques, typically on extremities, often overlying osseous defects. (Fig. 74.6a). BA also may have the appearance of a cellulitic plaque. Lesions may develop ulceration, discharge, crusting, and may be tender, associated with regional lymphadenopathy.<sup>27</sup> Bone pains are frequent in the forearms or legs. Bartonella-related pseudomembranous angiomatous papillomatosis of the oral cavity has been

\*c+

\*d+

**Fig. 74.6:** Bacillary angiomatosis: (a) pre-treatment, (b) post-treatment with erythromycin.

described.<sup>28,29</sup> Because extensive visceral lesions may occur, skin lesions of BA must be regarded as a marker of possible internal involvement. Symptoms resulting from visceral involvement, including abdominal pain, vomiting, jaundice (peliosis hepatis), tenesmus, bloody diarrhea (colonic bacillary angiomatosis); psychiatric symptoms and difficulty in breathing secondary to laryngeal obstruction may occur. Diagnosis is most often based on clinical features coupled with biopsies of lesions and appropriate staining (Warthin Starry silver staining). Erythromycin (500 mg four times a day) is drug of choice to be given for 3–4 weeks (Fig. 74.6b). Tetracyclines are the first alternative. A combination

of doxycycline (100 mg twice a day) plus rifampicin (300 mg bid) may be used in patients with severe disease. Clarithromycin, azithromycin, chloramphenicol, ciprofloxacin, trimethoprim sulfamethoxazole, rifampin, isoniazid, and gentamicin combined with either doxycycline or ciprofloxacin produce good clinical responses. Cryotherapy, electrodesiccation, curettage, and surgical excision of solitary cutaneous lesions can be useful as adjunctive therapy.<sup>30</sup> Prevention of bacillary angiomatosis associated with *B. henselae* infection involves avoidance of contact with cats, while for *B. quintana* infection it involves delousing procedures. Use of macrolides for *Mycobacterium avium-intracellulare* prophylaxis in patients infected with HIV is protective against bacillary angiomatosis. Prognosis of bacillary angiomatosis is excellent because antibiotics are curative in most patients. Pitfalls include failure to distinguish KS (potentially life threatening) from BA.<sup>30</sup>

**Cutaneous tuberculosis (TB)** accounts for 0.14% of all cases of tuberculosis.<sup>31,32</sup> Although TB is a common disease in HIV-infected patients, exclusive cutaneous presentation is not common. The clinical presentation is diverse including scrofula, scattered violaceous papules, keratotic papules, nodules, tuberculides, and palmar or plantar keratoderma. An uncommon form of TB, tuberculosis cutis miliaris acuta generalisata, has reemerged among HIV-infected patients in recent years.<sup>33</sup> The clinical appearance of the lesions is not always characteristic and culture positivity for *M. tuberculosis* is not always obtained because skin lesions are typically paucibacillary. Marfatia et al. reported a case of non-healing perianal ulcer in an HIV-positive patient, who was not responding to antibiotics and anti-herpetic therapy [Fig. 74.7].<sup>34</sup> On further investigation, a swab from the ulcer showed acid fast bacilli (bacillary index 2+) on Ziehl–Neelson (ZN) staining which confirmed the diagnosis of tuberculous ulcer. The ulcer healed completely with 6 months of anti-tubercular treatment.<sup>34</sup>

**Fig. 74.7:** Tubercular perianal ulcer.

Atypical mycobacterial skin disease is usually due to *Mycobacterium avium intracellulare*. It manifests as violaceous papules, nodules, and ulcers as part of disseminated infection in patients with CD4 count  $< 50/\mu\text{L}$ . Primary cutaneous *M. avium* complex infection manifesting as sporotrichosis like lesions was also described in a patient with AIDS. Skin lesions have also been reported with *M. chelonae*, *M. fortuitum*, *M. kansasii*, *M. haemophilum*, and *M. marinum*. *M. haemophilum* infection presents as violaceous draining nodules and superficial ulcers on extremities, trunk, head, and genitalia. *M. kansasii* produces acneiform papules and indurated crusted plaques. They are treated with macrolides and ethambutol.

## FUNGAL INFECTIONS

The importance of fungal infections among HIV-positive patients was recognized in the early days of AIDS epidemic. The spectrum of illness ranges from asymptomatic mucosal candidiasis to overwhelming disseminated infection and life-threatening meningitis.

### Candidiasis

Mucocutaneous candidiasis occurs in three forms in persons infected with HIV: oropharyngeal, esophageal, and vulvovaginal disease. Oropharyngeal candidiasis is the most frequent opportunistic fungal infection affecting more than 90% of HIV-positive patients at some point during the progression of their disease. Esophageal candidiasis is reported in approximately 10% of patients with AIDS and is capable of producing incapacitating illness, wasting syndrome, and malnutrition.

Most common cause of oropharyngeal candidiasis is *Candida albicans* in 77–100% patients. It is an imperfect diploid dimorphic fungus that resides as a commensal in gastrointestinal tract and mucosae. Others are infected with non-albicans species like *C. tropicalis*, *C. parapsilosis*, *C. guilliermondii*, *C. glabrata*, and *C. dubliniensis*. *C. dubliniensis* has been specifically associated with oropharyngeal candidiasis in HIV. Clinically, oropharyngeal candidiasis presents as pseudomembranous (thrush), atrophic (erythematous), hyperplastic forms and as angular cheilitis. Pseudomembranous candidiasis is most common. Thrush usually occurs with CD4 counts of  $< 300$  cells/ $\mu\text{L}$ . Symptoms of thrush are variable ranging from sore painful mouth, burning tongue, and dysphagia. It appears as cottage cheese like, creamy white exudative plaques on the tongue, which can be easily removed and leaves an inflammatory erythematous surface. Erythematous oral candidiasis presents as one or more flat, red, subtle lesions on the dorsal surface of the hard or the soft palate. The dorsum of the tongue may show loss of filiform papillae. Oropharyngeal cultures are not diagnostic as colonization is common. A KOH preparation will show pseudohyphae and budding yeast but are not mandatory for diagnosis. A presumptive diagnosis of oropharyngeal candidiasis can be made by visual detection of characteristic lesions (Fig. 74.8 a,b,c).

\*c+

\*d+

\*e+

**Fig. 74.8:** Candidiasis (a) oral candidiasis with angular cheilitis, (b) cottage cheese like creamy white exudative plaques on the tongue, (c) esophageal candidiasis.

Esophageal candidiasis is an AIDS-defining condition, generally occurring in individuals with CD4 counts of  $<100$  cells/ $\mu\text{L}$ . It is usually accompanied by oropharyngeal candidiasis. Patients may complain of retrosternal burning sensation and odynophagia. In as many as 40% of patients with oropharyngeal candidiasis, esophageal involvement may be asymptomatic.<sup>35</sup> Persistent dysphagia even after disappearance of candidiasis after treatment warrants endoscopy to rule out other causes of esophagitis like cytomegalovirus, herpes simplex virus, tuberculous, and aphthous ulcers.

Uncomplicated vulvovaginal candidiasis affects 90% of HIV-infected women and occurs at higher CD4 counts than for other forms of candidiasis.<sup>36</sup> Recent studies indicate that candidal vaginitis, even if more frequent in HIV-infected women, is clinically similar to that experienced by HIV-negative women and does not appear to be of increased clinical severity.<sup>37</sup> Vulvovaginal candidiasis generally presents with marked itching, watery to curd-like discharge, vaginal erythema with adherent white discharge, dyspareunia, external dysuria, erythema, and swelling of labia and vulva with discrete pustulopapular peripheral lesions. The cervix usually appears normal. Symptoms typically exacerbate the week preceding menses with some relief once menstrual flow begins. A KOH preparation should be made to confirm the diagnosis.

Chronic fingernail candidal paronychia with secondary nail dystrophy (onychchia) is also common in HIV-infected children. Proximal nail fold inflammation is usually associated with proximal onycholysis or onychomycosis due to candida.

Milder episodes respond to topical therapy with nystatin, clotrimazole troches. Topical therapies are effective for uncomplicated oropharyngeal candidiasis; however, patients relapse more quickly than those treated with oral systemic antifungal therapy like ketoconazole, itraconazole or fluconazole.

Fluconazole is preferred over itraconazole or ketoconazole because its absorption is not dependent on gastric acidity or food intake, and patients are more likely to remain disease free during the fluconazole follow-up period. Fluconazole is recommended in a dose of 100–200 mg daily for 10–14 days. For maintenance therapy, 50–100 mg on alternate days is recommended for patients with less advanced disease or daily for patients with relapse or AIDS.

For vulvovaginal candidiasis, clotrimazole 1% cream or 5 g intravaginally for 7–14 days, or one 100 mg vaginal tab for 7 days is quite effective. Systemic therapy consists of fluconazole 150 mg as a single dose. Primary prophylaxis is not recommended due to cost, potential for development of resistance, drug interactions, and efficacy of therapy for acute disease.

## Dermatophytosis

Dermatophytosis in HIV patients is more varied, extensive, and atypical than in immunocompetent individuals. Most common is infection with *Trichophyton rubrum*. The lesions may be atypical with lack of active edge and central scaling (anergic form). They respond to topical and systemic anti-fungal therapy with imidazoles and triazoles. *Trichophyton rubrum* causes proximal

subungual onychomycosis, an infection of the undersurface of proximal nail plate. It is usually a sign of HIV disease and its diagnosis is an indication for HIV testing.

## Seborrheic Dermatitis

An increased colonization of *Malassezia furfur* has been reported in patients with HIV infection. Pityriasis versicolor and pityrosporum folliculitis arise from overgrowth of *M. furfur*. It is also thought to have a significant role in the pathogenesis of seborrheic dermatitis.<sup>38</sup> Seborrheic dermatitis (SD) is very common HIV-related opportunistic event and is usually a marker for early HIV disease (CD4 counts  $> 500$ ). Up to 85% of HIV-infected people experience seborrheic dermatitis at some time during the course of HIV infection. *Pityrosporum ovale*, a lipophilic yeast of the *Malassezia* genus, has also been implicated in the development of this condition. Clinically, it appears as erythema with yellow waxy scales most typically on scalp, around eyebrows, ears, and beard area but in HIV-positive individuals, rash also appears on chest, back, axilla, and groins.

Treatment includes topical application of mild-to-medium potency corticosteroids as well as topical anti-fungal creams such as the imidazole derivatives that have good activity against yeasts. For scalp, shampoos that contain coal tar, selenium sulfide, salicylic acid, and zinc pyrithione as well as ketoconazole are very effective.<sup>39</sup>

## Deep Fungal Infections

The commonly encountered ones are candidiasis, cryptococcosis, and histoplasmosis. Other fungal infections like coccidioidomycosis and *Penicilliosis marneffei* are seen usually in geographically restricted areas. *Penicilliosis marneffei* has been extensively reported in Thailand and South China, and more recently from North-East India. Coccidioidomycosis has never been reported in South-East Asia.

## Cryptococcosis

*Cryptococcus neoformans* is isolated in majority of AIDS patients because this variety is ubiquitous and predominantly affects immunocompromised hosts. It grows readily from soil contaminated with avian excreta, particularly those of pigeons. More than three fourths of the cases associated with AIDS develop this infection when the CD4 T-lymphocyte count falls below 50 cells/ $\mu\text{L}$ . CNS is the most common site of disseminated cryptococcal infection. Lung is most likely the portal of entry. Cutaneous cryptococcosis is a sign of dissemination present in approximately 10% of cases.<sup>40</sup>

The cutaneous lesions vary greatly in morphology and mimic many other dermatologic entities. They are usually characterized by multiple, discrete, flesh-to-red colored papules varying in size from 1 to 6 mm and often slightly umbilicated, resembling molluscum contagiosum. The lesions may appear as papules, tumors, vesicles, plaques, abscesses, cellulitis, purpura, draining

sinuses, ulcers, bullae, or subcutaneous swelling. It is often necessary to take biopsy and culture skin lesions resembling molluscum contagiosum to exclude the more serious condition of cryptococcosis.<sup>41</sup>

Cutaneous disease should be presumed to be disseminated and an appropriate workup for systemic involvement is essential. This includes a thorough history and physical examination, chest radiography or CT scanning to evaluate pulmonary involvement, lumbar puncture, and imaging of the CNS, and other studies as indicated. Primary cutaneous disease can be treated with oral fluconazole or itraconazole.

### Penicilliosis

It is an infection caused by *Penicillium marneffei*, a dimorphic fungus endemic to Southeast Asia and the southern part of China. Persons affected by penicilliosis usually have AIDS with low CD4 lymphocyte counts, typically <100 cells/ $\mu$ L. The most common presentation is a disseminated infection manifested by fever, skin lesions, anemia, generalized lymphadenopathy, and hepatomegaly. Lesions are present in approximately two thirds of cases and can be varied in appearance. Generalized papular eruptions, central umbilicated papules resembling those of molluscum contagiosum, acne-like lesions and folliculitis all may occur. Skin lesions commonly occur on the face, trunk, and extremities. Subcutaneous nodules can be occasionally seen. Diagnosis usually is made by identification of fungi from clinical specimens. Treatment with amphotericin B with or without flucytosine, or itraconazole, is the treatment of choice.

## PARASITIC INFECTIONS

### Scabies

Scabies can occur at any CD4 count, but the manifestations are more severe at lower CD4 counts.<sup>42</sup> In a study of 286 HIV-infected patients, scabies was seen in 4% of cases.<sup>43</sup> Not always as crusted (Norwegian) scabies, it can manifest in both typical and atypical forms. Although the classic, hyperkeratotic, papules, and plaques are most common, reported cases have ranged in spectrum from crusting with pruritus to a pruritic, papular dermatitis and those resembling Darier disease or psoriasis.<sup>44</sup> Nail thickening is typical in patients with crusted scabies.<sup>45</sup> Patients with Norwegian scabies can be infested with hundreds to thousands of adult female mites. This type of scabies is highly contagious and may spread rapidly through patients in an institutionalized setting.<sup>46</sup> When generalized papular, crusted, or eczematoid lesions are observed in HIV-positive patients, particularly with CD4 count less than 200/ $\mu$ L, scabies should be included in the differential diagnosis.<sup>47</sup>

Therapy requires the sequential use of scabicides, usually over a longer period than is required to clear an ordinary case of scabies. Compliance is a concern and the scabicides are best administered under supervision whenever possible. Isolating the index patient and treating the environment of patients with crusted or atypical

scabies is much more significant than in ordinary scabies. The transmission from an index patient with crusted scabies to other patients, healthcare workers, etc. is common.<sup>48</sup> Protective measures and early diagnosis and therapy are essential.<sup>48</sup>

### Leishmaniasis

*Leishmania* species can cause a wide spectrum of cutaneous lesions in HIV-positive patients ranging from localized cutaneous, mucosal, mucocutaneous, diffuse cutaneous, visceral or post-kala-azar dermal leishmaniasis (PKDL).<sup>49</sup> There is support for the suggestion that dissemination of lesions is more determined by host immunogenic status than by the virulence of the parasite species involved. Immune suppression caused by HIV infection is an important factor for atypical presentation and widespread progression of cutaneous leishmaniasis.<sup>50</sup> It also weakens response to classic treatment.<sup>51</sup>

In India, *Leishmania donovani* has been reported in PKDL associated with HIV. *Leishmania pifanoi* and *Leishmania infantum* have also been found in cutaneous leishmaniasis (CL) with HIV co-infection.<sup>50</sup> An HIV-infected patient has atypical and severe clinical presentation of CL in terms of sites and types of lesions (papulonodular) in relation to number of CD4 cells (>200).<sup>51</sup> Mucosal lesions of CL in an HIV patient should not be considered as mucocutaneous leishmaniasis (MCL) because parasites commonly disseminate and involve nasal and oral mucosa.<sup>52,53</sup> Diffuse (disseminated) cutaneous leishmaniasis with HIV co-infection is emerging as an extremely serious new disease. It has even been reported as the first manifestation leading to the diagnosis of HIV infection. In India, there is a high risk of mistaking diffuse cutaneous leishmaniasis especially for lepromatous leprosy since the latter is also endemic.<sup>51</sup>

There are two common therapies for leishmaniasis containing antimony (pentavalent antimonials), meglumine antimoniate and sodium stibogluconate.<sup>54</sup> HIV co-infected patients can be treated by various drugs like amphotericin-B, ketoconazole, miltefosine.<sup>55,56</sup> Protease inhibitors have been found to be active against leishmania species in two *in vitro* studies in Canada and India.<sup>57</sup> It is reported that ART therapy shows no difference in outcomes and relapses compared with those not on therapy.

### ICHTHYOSIFORM DERMATOSES

The spectrum of papulosquamous disorders in HIV patients encompasses xerosis, eczema, seborrheic dermatitis, psoriasis, and Reiter syndrome. In a study of 286 HIV-infected patients xerosis was found in 3%, eczema in 8%, and seborrheic dermatitis in 8%.<sup>43</sup> There are reports of chronic photodermatitis associated with HIV infection.<sup>58</sup> Cases of pityriasis rubra pilaris in the setting of HIV infection have been reported.<sup>59</sup>

HIV-infected patients commonly complain of increasing dryness of the skin (xerosis), which has been seen in up to 30% of patients.<sup>60</sup>

Severe intractable pruritus with eosinophilia may indicate a subset of HIV-infected patients with hyperactivation of humoral

immunity and augmented viral load.<sup>4</sup> Pruritus and xerosis are also the side effects of protease inhibitors.<sup>4</sup>

Typically, xerosis is most prominent on the anterior aspect of lower legs, but it may be quite widespread. Dry and thickened polygonal skin-colored scaling, as seen in acquired ichthyosis, is also seen in patients with advanced HIV disease. Thickening of the palms and soles may be present as well.<sup>61</sup> It becomes more severe with disease progression as CD4 counts decline.

Patients should apply mild topical steroid ointments (1.0–2.5% hydrocortisone or 0.025% triamcinolone) to the dermatitic areas three times a day and should cover all dry areas of the body with a moisturizing lotion or cream.<sup>61,62</sup>

## PSORIASIS

The prevalence of psoriasis in HIV-infected individuals is the same or slightly higher than seen in non-infected individuals, but its clinical presentation can be more florid, severe, and atypical.<sup>63,64</sup> Prevalence of psoriasis in HIV is 5–6%.<sup>65</sup> HIV-associated psoriasis appears paradoxical, being a T-cell-mediated disease in the face of decreasing T-cell counts. Furthermore, psoriasis is generally mediated by type-1 cytokines, whereas in HIV, type 2 cytokines tend to predominate.<sup>66</sup> Various theories for the worsening of psoriasis in HIV include immune dysregulation, an increase in viral and bacterial antigens in the skin, genetic susceptibility, and direct effects of HIV proteins on keratinocytes.<sup>67</sup>

Increase in the incidence of arthritis associated with psoriasis is seen as compared to the general population. Also, a higher frequency of guttate and inverse psoriasis as well as cases of generalized erythrodermic type of psoriasis have been reported in HIV-positive patients. Pruritus may be a serious problem for the HIV-infected patient with psoriasis. With scratching, secondary infection of excoriated psoriatic plaques with *S. aureus* may occur. Erythrodermic psoriasis in HIV-infected patients may be a sign of *S. aureus* septicemia and the psoriasis may improve dramatically with only intravenous antibiotics.<sup>61</sup>

The differential diagnosis of psoriasis include seborrheic dermatitis, atopic dermatitis, dermatophytosis, drug-induced eruption, and mycosis fungoides.<sup>4</sup>

**Fig. 74.9:** Extensive psoriasis in AIDS patient refractory to standard antipsoriatic treatment.

Psoriasis in HIV-positive patients is often refractory to standard anti-psoriatic treatment (Fig. 74.9).<sup>66</sup> HIV-positive patients who have either been started or restarted on ART show rapid improvement of psoriasis. Despite initial reports of enhanced HIV replication and immune suppression caused by UV light treatment, subsequent studies have not found the use of UVB or PUVA to accelerate HIV disease progression and have been used with variable success in the treatment of psoriasis. Systemic agents for psoriasis like methotrexate, azathioprine, and cyclosporine A, which cause non-specific or specific T-cell immunosuppression, should be avoided.<sup>68</sup> Cyclosporine and methotrexate have caused serious complications in HIV-infected patients such as leukopenia and fulminant Kaposi sarcoma.<sup>61</sup> Retinoids, especially etretinate, appear useful to help with moderate to severe psoriasis and do not cause immunosuppression.<sup>68</sup> Etanercept has been used with good effect in HIV-related psoriasis and arthritis in 1 patient but had to be discontinued because of the serious complications.<sup>4</sup>

## REITER SYNDROME

Classic Reiter syndrome (RS) is a parainfectious reaction associated with urogenital (*Chlamydia trachomatis*) or enteric infections (Shigella, Yersinia, Campylobacter, and Salmonella).<sup>68</sup> It consists of the triad of conjunctivitis, urethritis, and seronegative asymmetrical oligoarthritis. Whether the incidence of RS is increased in HIV infection, or whether HIV infection merely permits the expression or exacerbates the features of RS, is not known.<sup>69</sup> Immune dysfunction, cellular lymphokines, arthritogenic pathogens (Salmonella, Shigella, Yersinia, Campylobacter, and Giardia), and the direct effect of HIV have all been proposed as explanations. The increase in CD8 counts is believed to be important. Another hypothesis is that the HIV triggers an immune complex reaction. Finally, HIV may have direct effect on the synovial tissue. HIV-positive patients with RS also have a high incidence of HLA-B27 positivity.<sup>68</sup>

The classic cutaneous lesions of RS occur similarly in the HIV-associated RS as they occur in HIV-negative patients. They include hyperkeratotic areas over palms and soles known as keratoderma blennorrhagicum, circinate balanitis, conjunctivitis, which is generally transient and culture negative; urethritis/cervicitis; or diarrhea. The arthritis is inflammatory and usually affects one to five large joints of the lower extremities. Small joint involvement or axial arthritis is uncommon. Nails may show extensive subungual debris, may be horizontally ridged, and during severe flares, the nail plate may be so dystrophic as to appear absent. In the groin and axillae, red plaques identical to those seen in seborrheic dermatitis and psoriasis can be present.<sup>69</sup> Evanescent and often asymptomatic oral erosions may be present. Geographic tongue (i.e., showing migratory white patches) may also be found in patients with RS.

These patients may be treated with NSAIDs, sulfasalazine, or prednisolone. Etretinate, followed by RePUVA, proved to be the most effective systemic therapy, with only rare adverse effects.<sup>69</sup>

Treatment with cyclosporine A is moderately effective and not associated with progression of AIDS. There are reports of patients developing adverse effects such as *Pneumocystis jiroveci* pneumonia (PCP), Kaposi sarcoma (KS) on treatment with methotrexate.

## PRURITIC ERUPTIONS

Several chronically itchy papular and papulopustular eruptions, variously referred to as pruritic papular eruptions (PPE) of HIV infection, “itchy red bump disease,” papular urticaria, prurigo nodularis and insect bite reactions, have been reported in HIV-infected patients. PPE probably represents a heterogeneous spectrum of papular and papulopustular skin eruptions with similar or overlapping clinical and histological features and response to therapy.<sup>70</sup>

Pruritic eruptions can be classified as follicular, non-follicular, papular eruptions and others.

### Follicular Pruritic Eruptions

They can be eosinophilic folliculitis (EF), Demodex folliculitis, and Pityrosporum folliculitis.<sup>71</sup>

#### Eosinophilic Folliculitis

HIV-associated eosinophilic folliculitis is one of the variants of EF (eosinophilic pustular folliculitis or Ofuji disease). It is an idiopathic dermatitis that occurs in HIV-infected individuals with different clinical manifestations but with a distinctive histological feature characterized by predominantly eosinophilic infiltrate in the follicular infundibula.<sup>72</sup> The prevalence is uncertain, although one series reported it in 9% of HIV patients.<sup>73</sup> EF is more common in advanced HIV with CD4 <250/ $\mu$ L. Therefore, it identifies patients at immediate risk of developing opportunistic infections.<sup>4</sup> The cause is unknown but Th2 cytokines (IL-4, IL-5), RANTES, and eotaxin are increased in the lesional skin.<sup>74</sup> Foscarnet has also been implicated in development of eosinophilic folliculitis.<sup>75</sup>

Eosinophilic folliculitis (EF) presents as erythematous urticarial papules, pustules, and/or papules with pinpoint vesicles or perifollicular pustules on the face, neck, upper chest, and back, characteristically above the nipple line. The upper arms, eyelids, post-auricular areas, and scalp are often involved. It mimics staphylococcal or pityrosporum folliculitis, and acne vulgaris, with which it can co-exist.<sup>4</sup>

Pruritus is usually severe and unrelieved by anti-histamines, and tends to be chronic with occasional periods of remission. Laboratory examination may reveal elevated IgE levels and peripheral eosinophilia.<sup>70</sup>

Eosinophilic folliculitis frequently responds to UVB phototherapy and isotretinoin. There are reports that EF may also improve with cetirizine, itraconazole, metronidazole, and diaminodiphenyl sulfone. Ivermectin and long-term application of permethrin are used with some success implying a possible role for Demodex mites in the pathogenesis.<sup>72,74</sup>

#### Demodex Folliculitis

Mites such as *Demodex folliculorum* and *Demodex brevis* are natural hosts of the human pilosebaceous follicle and are ubiquitous obligatory ectoparasites of man. Most authors believe that the altered immune system favors the growth of this usually saprophytic agent so that it eventually causes a skin disorder. On the other hand, some authors suspect an unusual hypersensitivity against the mite itself.<sup>76</sup>

Demodex infestation can present as a mild form resembling pityriasis folliculorum and in some cases, rosacea-like lesions are seen.<sup>77</sup> The mild form presents as a pruritic papular eruption mainly limited to the face and neck.

Demodicidosis can be treated topically with 1% permethrin, 10% sulfur, 1% lindane, 5% benzoyl peroxide, 10% benzyl benzoate, or pilocarpine gel. Oral ivermectin and metronidazole can also be used.<sup>78</sup>

#### Pityrosporum Folliculitis (PF)

PF or malassezia folliculitis is caused by the invasion of the hair follicle by *Malassezia furfur*. Its development appears to have an immune component, and has been reported to occur mostly in immunosuppressed individuals. Moreover, the eosinophilic folliculitis seen in patients with HIV and AIDS may also be marked by colonization of the follicles with *Malassezia* yeasts.<sup>79</sup>

The classic presentation of PF is a follicular pattern of papulopustules arising in crops on the upper back, shoulders, chest, and sometimes on the scalp. The lesions are pruritic and they have a tendency to recur. Therapy must be directed both at restraining yeast overgrowth as well as tackling predisposing factors, to avoid recurrence.<sup>79</sup>

Specific treatment for *Malassezia* folliculitis comprises of oral azole antifungals in which itraconazole 200 mg PO once-daily  $\times$  4 weeks is preferred<sup>17</sup> and topical anti-fungal agents including 2% ketoconazole or ciclopirox creams or econazole foaming solution.<sup>79</sup>

### Non-follicular Eruptions

Non-follicular pruritic eruptions can be sub-classified into primary pruritic eruptions (viz. scabies, insect bites, transient acantholytic dermatoses, granuloma annulare, and prurigo nodularis) and eczematous eruptions (viz. atopic dermatitis, seborrheic dermatitis, nummular eczema, asteatotic eczema, photodermatitis, and drug eruptions).<sup>71</sup>

#### Pruritic Papular Eruption (PPE)

It is the most common cutaneous manifestation in HIV-infected patients. Anywhere between 18% and 46% of patients with HIV have this condition at sometime.<sup>80</sup> PPE can be regarded as a cutaneous marker of advanced HIV infection,<sup>81</sup> occurring at CD4 T-cell counts below 100–200/ $\mu$ L.

**Fig. 74.10:** Pruritic papular eruptions.

The etiology of this distressing condition is unclear, although an exaggerated response to an exogenous agent, such as arthropod bites, may underlie the pathogenesis. It is characterized by chronic pruritus and symmetric papular eruptions with excoriations on the trunk and extremities, with the absence of other definable causes of itching in an HIV-infected patient (Fig. 74.10). Patients frequently have prurigo nodules if the condition is long-standing. Lichenified patches and plaques on the arms and legs may be seen, probably representing an AIDS-associated, late-onset, atopic dermatitis.<sup>70</sup> PPE follows a chronic waxing and waning course, and may have an associated peripheral eosinophilia and elevated levels of IgE.<sup>70</sup> Identifying PPE's association with the immune dysregulation of HIV and distinguishing this condition from other pruritic disorders found in HIV-infected patients is important for optimal management.<sup>4</sup> Strictly it is diagnosis of exclusion.

Histopathologic examination in PPE reveals hyperkeratosis, acanthosis, focal dyskeratotic, and necrotic cells in the epidermis, and dermal fibrosis with proliferation of factor XIIIa-positive dermal dendrocytes. The dermal infiltrate also includes lymphocytes, plasma cells, eosinophils, and mast cells.<sup>4</sup>

Topical steroids, emollients, and oral antihistaminics should be the first line of management. Failing this phototherapy can be commenced. Several studies have shown that ultraviolet B (UVB) phototherapy is helpful for the treatment of HIV-associated pruritus.<sup>4</sup> The itching generally diminishes after 4–8 weeks of treatment. Pentoxifylline (usual dose recommended is 400mg three times daily for 8 weeks) and indomethacin have recently been reported to be effective in relieving HIV-related pruritus, although this has not been confirmed in randomized, controlled studies.<sup>70</sup>

## Pruritus in HIV

Patients with HIV infection commonly have elevated circulating IgE antibodies. Basophils have been shown to be hyper-releasable in HIV disease, and the mast cells in some patients are presumed to have a lower threshold for release of histamine, with attendant inflammatory reaction and pruritus. Patients with HIV disease

may also have direct neural infection with HIV leading to neural irritation and enhanced sensations of itching. Sometimes, autonomic dysfunction is associated with diminished sweating and sebaceous gland secretion that worsens xerosis and itching. In addition, patients infected with HIV may be under considerable stress, also leading to urticaria and itching. Finally, patients with HIV infection may develop pruritus secondary to underlying circulating pruritogens associated with different systemic disorders, such as chronic liver disease, chronic renal disease or lymphoma.<sup>82</sup>

## HYPERPIGMENTATION DUE TO HIV

Progressive pigmentation of the skin, nails, and mucosa is seen among HIV-positive patients. This can be attributed to opportunistic infections of the adrenal cortex culminating in Addison disease; or drug-induced hyperpigmentation due to zidovudine and antifungals like ketoconazole.<sup>70</sup> Alternatively, pigmentation may occur in HIV-seropositive patients who show no alterations in serum cortisone or ACTH levels and in whom drug-related etiology can be ruled out.<sup>71</sup> Rangnathan et al. studied 1700 HIV/AIDS patients, oral hyperpigmentation was seen in 24.6% cases. It was seen that patients with a CD4<sup>+</sup> <200/ $\mu$ L (54.7%) displayed pigmentation significantly ( $p < 0.05$ ) more often than those with a CD4<sup>+</sup> >200/ $\mu$ L (45.3%).<sup>72</sup>

In HIV disease, the immune system is dysregulated, leading to the elevation of interleukins (IL-1 and 6) and tumor necrosis factor- $\alpha$ , which leads to the release of  $\alpha$  melanocyte-stimulating hormone ( $\alpha$ -MSH) from the anterior pituitary. IL-1 upregulates  $\alpha$ -MSH receptor expression by melanocytes, and causes pigmentation.<sup>72</sup> It has been further suggested that cutaneous manifestations, including hyperpigmentation, might be a marker of immune suppression, since it was associated with a low CD4+ cell count.<sup>72,4</sup>

The hyperpigmented lesions due to HIV disease are diffuse, grey or brown, and generally multifocal.<sup>71</sup> Treatment with zidovudine (AZT) may result in hyperpigmentation of the nails, oral mucosa, and skin. The initial manifestation of hyperpigmentation is usually a bluish discoloration of the lunulae (proximal white portions) of the nails, most prominently on the thumb nails. This appears about 1 month after AZT therapy begins. Bilateral black pigmentation of the lateral mid-tongue has also been observed. The degree of hyperpigmentation of the nails and skin is related to dosage of AZT.

No melanocytic proliferation is evident on histopathological examination.

The lesions are asymptomatic and there is no specific treatment.<sup>71</sup> Cutaneous hyperpigmentation on the face may improve by avoiding sun exposure and using a sunscreen with SPF 15 or higher.<sup>73</sup>

## KAPOSI SARCOMA (KS)

Persons infected with HIV are at an increased risk for all cancers known or suspected to have an infectious cause, an effect believed

to be primarily mediated by lowered host immunity via the depletion of CD4<sup>+</sup> T cells.<sup>83</sup> Kaposi sarcoma (KS) and non-Hodgkin lymphoma were recognized as AIDS-defining illnesses early in the HIV epidemic. KS–AIDS has as aggressive course in HIV, especially among homosexuals, with an average age of 20–40 years.<sup>84</sup>

The incidence of Kaposi sarcoma has fallen markedly in the recent times, although its prevalence has not, Kaposi sarcoma originally accounted for as many as 35% of patients with AIDS, an incidence that has been declining with early detection of HIV infection.<sup>84</sup> Factors linked to KS include male gender, the HLA-DR5 genetic marker, abuse of nitrite drugs, exposure to semen or anal sex, or to several other viruses. HHV-8 is the most prominent of many viruses considered as a potential causal agent.<sup>85</sup> HHV-8 may be transmitted sexually, probably more by feco-oral route or the ejaculate rather than blood in HIV-positive homosexual men.<sup>4</sup>

Four different epidemiological forms of KS have been described that have identical histological features but developed in specific populations and have different sites of involvement and rates of progression.<sup>86</sup> HIV-related KS is known as epidemic KS.<sup>84</sup> Patients with AIDS-related KS can be divided into four groups: (i) those with no prior or co-existent opportunistic infection (OI), no systemic symptoms, CD4  $\geq 300$  cells/ $\mu$ L (median survival, 31 months); (ii) those with no prior or coexistent OI, no systemic symptoms, and CD4  $< 300$  cells/ $\mu$ L (median survival, 20 months); (iii) those with no prior or co-existent OI and presence of systemic symptoms (median survival, 15 months); and (iv) those with prior or co-existent OI (median survival, 7 months).<sup>87</sup> AIDS-related KS varies from minimal to fulminant disease.<sup>88</sup> It may be disseminated involving lymph nodes, viscera, and mucosa as well as skin.<sup>86</sup>

Cutaneous KS is multicentric and often involves the face, oral mucosa, palate, and genitalia.<sup>4</sup> Lesions may be multiple, follow skin creases, tend to be linear or to Koebnerize.<sup>4</sup>

Lymphedema may eventuate. The classical lesion is a purple patch, plaque or nodule, which may ulcerate (Fig. 74.11 a&b).<sup>4</sup>

The rate of progression varies from patient to patient and may not be related to the level of immunosuppression. Cutaneous involvement is the most common presentation (>90%). Other than the skin and oral mucosa, lungs (20%), gastrointestinal tract (40%) and lymph nodes are the sites commonly involved. Phimosis may occur if the lesion is located on the foreskin. Skin biopsy and immunohistochemical investigations are crucial to confirm the diagnosis of KS.<sup>84</sup>

Patients with KS–AIDS usually die from associated OIs or from gastrointestinal Kaposi sarcoma with hemorrhage. The mean survival rate of patients with KS–AIDS has been approximately 15–24 months, although the introduction of apparent immune system reconstitution using ART has extended survival substantially.<sup>89</sup>

The response of Kaposi sarcoma to ART is unpredictable, specific local or systemic therapy is often instituted as well.<sup>86</sup> In addition to ART, excellent treatments exist for both localized disease (topical gel, radiotherapy, and intralesional therapy) and advanced disease (liposomal anthracyclines, paclitaxel). Patients

\*c+

\*d+

**Fig. 74.11:** (a) Kaposi sarcoma; (b) Kaposi sarcoma with tinea corporis.

with Kaposi sarcoma who have widespread mucocutaneous disease, lymphedema, or visceral disease are usually treated with systemic cytotoxic therapy.

Novel therapies that have become available to treat AIDS-related KS include angiogenesis inhibitors and anti-viral agents.<sup>85</sup> Biologic agents such as interferon-alpha are now considered first-line therapy for some patients with epidemic cutaneous Kaposi sarcoma.<sup>86</sup>

There are reports of successful treatment with paclitaxel and anti-retrovirals.<sup>84</sup>

### ADVERSE CUTANEOUS DRUG REACTIONS (ADR)

The incidence of adverse cutaneous drug eruptions to a variety of drugs is high in individuals with untreated HIV disease (100 times more common than in the general population) and it increases with advancing immunodeficiency.<sup>90</sup> Although the clinical manifestations of drug eruptions are extremely diverse in nature, it is important to recognize these, as some of the eruptions can be serious. It is often not possible to specify the responsible drug or the pathogenetic mechanism on the basis of the clinical

appearance alone because the skin responds in a limited manner to a wide variety of stimuli.<sup>91</sup>

The urticarial papules and the eczematous cutaneous lesions that we have observed in AIDS patients, can be attributed to the mediators of the type I hypersensitivity reaction, characterized by the production of antibodies (mainly IgE) in response to the allergen. Sulfonamides, anti-convulsants, and anti-mycobacterial drugs are commonly used in patients with HIV disease. Patients with HIV have a much greater rate of ADRs to these drug classes, including severe and life-threatening hypersensitivity reactions. Between 50% and 60% of untreated HIV- infected individuals given intravenous TMP-SMX develop an exanthematous eruption (often associated with fever) 1–2 weeks after starting therapy, an incidence 10 times higher than that in general population.

The early detection and treatment of cutaneous adverse drug reactions, plus identification of the causative agent, are essential to prevent the progression of the reaction, preventing additional exposures and ensuring the use of alternative medications for the current condition.

In most of the cases, the implicated or suspected drug should be discontinued. In some instances, such as with morbilliform eruptions, the offending drug can be continued, and the eruption may slowly resolve. In cases of urticaria/angioedema or early Stevens–Johnson syndrome/toxic epidermal necrolysis the reaction can be life threatening and so the drug should be discontinued immediately.

### Cutaneous Adverse Drug Reactions (ADRs) due to Antiretrovirals (ARV)

Lifelong multidrug therapy is required for near complete suppression of HIV-1 replication, thereby exposing patients to the risk of ADRs and drug toxicities.

In a review of over 1000 patients in a Swiss cohort that received combination ARV therapy, 47% and 27% of the patients were reported to have clinical and laboratory adverse events, respectively.<sup>92</sup> Cutaneous manifestations of ADRs can serve as a surrogate marker of internal involvement. Antiretrovirals can lead to short-term toxicities or long-term side effects:

**A. Short-term toxicities:** SJ syndrome, hypersensitivity.

**B. Long-term side effects:** Morphologic complications:

- Lipoatrophy (facial and of extremities)
- Lipoaccumulation/lipohypertrophy
- Breast enlargement
- Dorso-ventral fat pad
- Lipomas
- Cosmetic disfigurement

### Hypersensitivity

Drug hypersensitivity typically manifests as erythematous maculopapular or morbilliform, pruritic and confluent rash with or without fever. Rash is most prominent on the body and arms and begins after 1–2 weeks of therapy. Constitutional features like

fever are often prominent and can precede rash (with abacavir) or occur without rash. Other principal features include myalgia, fatigue, and mucosal ulceration. Less common features (<5%) are SJ syndrome or toxic epidermal necrolysis (TEN) (0.3%), anicteric hepatitis, hypotension, acute interstitial nephritis, and acute interstitial pneumonitis.<sup>93</sup>

All NNRTI (Nevirapine, Delavirdine, Efavirenz), NRTI (Abacavir) and PI (Amprenavir) are common ARVs that cause hypersensitivity. Nevirapine (NVP) has been associated with a skin rash in 32–48% of patients,<sup>94</sup> with comparatively high incidence of rash in the Asians.

The most common symptomatic side effect of nevirapine is rash, usually occurring in the first 6 weeks of treatment.<sup>95</sup> Nevirapine-associated skin reactions usually are mild to moderate but in some cases are severe and life threatening, like extensive maculopapular rash, Steven–Johnson syndrome (Fig. 74.12) and toxic epidermal necrolysis.<sup>96</sup> Rash may also accompany hepatotoxicity. Patients with rash should be evaluated carefully for signs of severe skin reaction and for liver toxicity. In case of severe skin, liver, or hypersensitivity reaction, nevirapine must be discontinued permanently.<sup>95</sup>

It has been shown that the appearance of NVP-associated rash seems to depend on the levels of NVP and can be significantly reduced with a lead-in treatment period of 200 mg daily dose for the first 2 weeks, followed by 200 mg twice daily.<sup>97</sup>

Marfatia et al. reported that the most common ADRs due to ART were cutaneous (44.4%), with nail hyperpigmentation in 14.4% and rash in 13.3%. Rash was mainly observed with nevirapine-based regimen and in one case with efavirenz (EFV)-based regimen. Nail and oral hyperpigmentation was attributed to AZT.<sup>98</sup>

About 50% of ARV hypersensitivity resolves spontaneously despite continuation of antiretroviral therapy. Therapy should be stopped if there is mucosal involvement, blistering, exfoliation, clinically significant hepatic dysfunction (e.g., tender

**Fig. 74.12:** Nevirapine-induced Stevens–Johnson syndrome.

hepatomegaly, aminotransferase concentrations greater than five times the baseline), fever ( $>39^{\circ}\text{C}$ ) or intolerable pruritus.<sup>99</sup> Glucocorticoids are ineffective for the prevention of nevirapine hypersensitivity. Rechallenge is possible for mild to moderate NNRTI hypersensitivity but not for abacavir, since several deaths have been attributed to abacavir rechallenge.

### Lipodystrophy Syndrome

The overall prevalence of lipodystrophy syndrome is about 50% after 12–18 months of therapy.<sup>100</sup> Sharma et al. studied 42 cases on stavudine-based regimen and 22.9% cases were found to have lipodystrophy, making it the second most common ADR due to stavudine, the commonest being peripheral neuropathy (39.6%).<sup>101</sup>

Main clinical features are peripheral fat loss (presumed lipoatrophy with loss of buccal fat and thinning of extremities and buttocks) and central fat accumulation within abdomen (crix –belly or protease paunch), breasts (gynecomastia), over dorsocervical spine (buffalo hump), and other peripheral lipomatosis. In adult males, there is an overall fat loss although fat accumulation may predominate.

Lipodystrophy syndrome is commonly seen with use of protease inhibitors. Indinavir and saquinavir can cause gynecomastia in males.

Lipodystrophy should not be diagnosed if patient has had a recent severe illness associated with weight loss.

Risk factors for lipodystrophy are genetic factors, low body weight before therapy, raised C-peptides and triglyceride concentrations after about 1 year, use of dual PI combination ritonavir-saquinavir and use of nucleotide analogue, stavudine. Other cutaneous reactions of ARV are (Table 74.1).

### General Principles of Management

To avoid adverse drug reactions, start drugs with non-overlapping toxicities and which have small risk of interaction with existing therapy. Always consider clinical settings such as pregnancy or pediatric age group, injecting drug user, chronic hepatitis B or C, hemophilia, and post-exposure prophylaxis.

In case adverse reaction develops, dose reductions are not advised because of potential for drug resistance. In patients with good control of viral replication, if possible, immediately switch to drug with different toxicity profile, if the etiology is certain. In patients with uncontrolled viral replication, stop the responsible

drug and initiate a new agent with different toxicity profile; but if possible aim for a new regimen with improved anti-viral activity.

After the adverse reaction has subsided, rechallenge should be medically supervised; but is contraindicated with hypersensitivity to abacavir; or if there is mucosal involvement; or rashes are of grades 3–4. Desensitization is probably inappropriate because of potential for induction of viral resistance.

### HAIR

Hair loss is common in patients with HIV-1 infection. The causes include chronic HIV-1 infection itself and recurrent secondary infections, nutritional deficiencies, immunologic and endocrine dysregulation, and exposure to multiple drugs. Histopathological examination conducted on hair samples of HIV-positive patients in USA showed that all patients had telogen effluvium.<sup>102</sup>

Softening, sudden graying, and straightening of the scalp hair may be observed. Some authors have reported silky hair (the “straight hair sign”) as a sign of HIV infection. Its pathogenesis is not known but some have reported it as being a manifestation of mitochondrial abnormality.<sup>103</sup> Alopecia areata may be associated with HIV disease and may be inflammatory and permanent. The apoptotic follicular stem cell population in higher proportion may represent a hair cycle disturbance in patients with diffuse alopecia related to HIV-1 infection.<sup>16</sup> Alopecia universalis is also reported. Patchy alopecia is a common finding in HIV-positive children. Occasionally, alopecia may be a dermatological manifestation of seroconversion. Elongation of eyelashes may be seen in HIV-positive individuals.<sup>16</sup> Acquired trichomegaly may be an early marker of HIV infection.<sup>104</sup> Acquired eyelashes hypertrichosis (AEH) in AIDS patients closely resembles hypertrichosis in porphyria cutanea tarda (PCT).<sup>105</sup>

Strands of hair may be used to predict the effectiveness of ART. Levels of protease inhibitors like indinavir in small hair samples are the strongest independent predictor of virologic success in a diverse group of HIV-infected adults. Hair samples offer a simple but accurate test as to whether the virus is sensitive to ART or not and also check the patients’ compliance.<sup>106</sup> Alopecia universalis is reported in patients under ART. Generalized alopecia can occur in patients with HIV who are treated with indinavir, a protease inhibitor.<sup>16</sup> Zidovudine can cause hypertrichosis including of the eye lashes. Hair loss is also reported with lamivudine, didanosine, stavudine, lopinavir, and ritonavir. Hair regrowth is seen after discontinuation of lopinavir and ritonavir.<sup>107</sup> Colebunders and Vandenbraeene have described curly hair (with lipodystrophy) during ART.<sup>108</sup>

Alopecia universalis associated with Grave disease has been reported in immune restoration disease.<sup>109</sup>

### NAILS

Criber et al. reported that nearly 70% of HIV-infected individuals have nail changes.<sup>110</sup>

Longitudinal ridges and pallor of the nail beds are the general effects of the chronic illness. Patients with AIDS or AIDS-related complex may develop Beau lines (transverse ridges)

**Table 74.1** Cutaneous Reactions of ARVs

Cutaneous reactions	Drug
Hypertrichosis	Zidovudine
Alopecia	Indinavir, didanosine
Nail hyperpigmentation	Zidovudine
Acute generalized pustular dermatoses	Protease inhibitors
Paronychia with lateral nailfold pyogenic granuloma-like lesions	Indinavir, zidovudine, lamivudine
Leukocytoclastic vasculitis	Zidovudine, didanosine

following episodes of severe illness.<sup>111</sup> Half and half nails, loss of lunula, leukonychia, onycholysis, onychoschizia, periungual erythema, longitudinal melanonychia, linear melanosis, and onychodystrophies are also seen in HIV.

Nail dyschromia in patients infected with HIV was first described in 1987 by Furth and Kazakis.<sup>112</sup> Blue nails are a sign of HIV infection.<sup>4</sup> Yellow discoloration of the distal portion of some nails is a frequent finding in HIV-infected patients. Although originally described under the diagnosis of yellow nail syndrome (YNS), the yellow discoloration of the nails observed with HIV infection is a different condition. Typical nail changes of YNS such as reduced nail growth, nail plate over curvature, scleronychia and loss of cuticles are not observed. Color changes can be preceded by opacification and decreased size or loss of lunulae. Onycholysis at the distal part of the lateral nail folds as well as transverse/longitudinal ridging can be present. Great toe nails are most commonly involved while the fingernails are only rarely affected. Asymmetrical involvement of several nails is usual. Yellow toe nail changes have been considered together with seborrheic dermatitis, oral hairy leukoplakia, and oral candidiasis as possible indicators of progression to established AIDS.<sup>111</sup>

Digital clubbing has been reported in infants with AIDS; it can also occur in adults. Patients with clubbing are younger, have significantly higher digital index (the ratio of the nail bed: distal phalanx circumference) and have longer duration of HIV disease. HIV infection should be considered in the differential diagnosis of acquired digital clubbing.<sup>113</sup> Psoriatic onychia is more common than in patients of psoriasis in the general population. Clinically there is faster appearance of onycholysis.<sup>114</sup> Miralles et al. have proposed a new category of pityriasis rubra pilaris (type 6) in AIDS patients where all nails show paronychia, subungual hyperkeratosis, and hyperplastic cuticles.<sup>115</sup>

A lichenoid dermatitis associated with nail changes has been described in a 39 year old man with AIDS. Splinter hemorrhages and periungual lichenoid papules were also present.<sup>111</sup>

Kaposi sarcoma can involve nail area. A periungual Kaposi sarcoma resembling chronic paronychia has been reported in a patient with AIDS. Subungual squamous cell carcinoma has also been frequently reported in AIDS, often in association with HPV 16.<sup>111</sup>

Diffuse nail pigmentation as well as longitudinal or transverse hyperpigmented bands are frequently seen in HIV-positive patients receiving zidovudine (in 40% of the patients) (Fig. 74.13). Multiple longitudinal melanonychia as well as hyperpigmented macules on the palms, soles and mucous membranes unrelated to AZT (zidovudine) treatment have also been described in AIDS. The serum level of  $\alpha$ -MSH was significantly increased in 1 patient.<sup>111</sup> Zidovudine can also lead to paronychia or pyogenic granuloma. Paronychia and ingrown toe nail are particular complications of indinavir.<sup>4</sup>

## ORAL MUCOSA

Nearly all HIV infected, untreated individuals experience disorders of the oropharynx during the course of the disease. They

**Fig. 74.13:** Zidovudine (AZT)-induced longitudinal hyperpigmented band on thumb nail.

can be due to infectious (already discussed) or non-infectious causes. Oral ulcers are the presenting clinical manifestations in 10–20% of HIV-positive patients. The detection of oropharyngeal disorders may be an indication for HIV serotesting.<sup>8</sup> Principle dermatological manifestations of HIV seroconversion include oral ulcerations and oropharyngeal candidiasis. Others like transient intraoral redness, erosions, and xerostomia are also commonly found in early HIV infection and seroconversion.<sup>4</sup>

Idiopathic aphthous ulcers in HIV-infected individuals tend to be large (>1 mm in diameter) in contrast to minor recurrent ulcerations in immunocompetent populations. They are painful ulcerations of the oral mucosa, hypopharynx, and esophagus. In some cases, they may be very extensive; often involving the tongue, gingiva and the lips, and pain upon swallowing may be so severe that rapid weight loss ensues.<sup>10</sup> They are recurrent and refractory to treatment. Zalcitabine (ddC) causes aphthous-like ulceration of the oropharynx and esophagus.<sup>8</sup> Thalidomide has proved useful for these (idiopathic as well as ddC induced aphthous ulcers) at a dose of 100 mg nightly for 2 weeks followed by maintenance therapy of 100 mg every 5 days, with monitoring for peripheral neuropathy.<sup>4</sup>

**Fig. 74.14:** HIV: Linear erythema of gums.

Other oropharyngeal manifestations in HIV-infected individuals include xerostomia (10%), exfoliative cheilitis (9%), patchy depapillation of tongue (6%), oral manifestations of Reiter syndrome, petechiae from thrombocytopenia, hyperpigmentation, oral melanotic macules and ulcers of uncertain causes, and rarely linear erythema of gums<sup>8</sup> (Fig. 74.14).

Xerosis and cheilitis are common with protease inhibitors.<sup>4</sup> Indinavir can also cause cheilitis. Oral corticosteroid therapy for oral ulceration in HIV-infected individuals raises concerns regarding increased immunosuppression with exacerbations of OIs and neoplasms such as HSV infections and Kaposi sarcoma and oropharyngeal candidiasis.<sup>8</sup> Foscarnet and interferon are also responsible for oral ulcerations. Didanosine causes dysgeusia and xerostomia. Dysgeusia and perioral paraesthesia are caused by amprenavir and ritonavir.<sup>4</sup>

### IMMUNE RECONSTITUTION INFLAMMATORY SYNDROME (IRIS)

A subgroup of ART treated patients will exhibit paradoxical deterioration in their clinical status, despite satisfactory control of viral replication and improvement in CD4 counts. This clinical deterioration, known as the immune restoration syndrome or immune reconstitution inflammatory syndrome (IRIS), is a result of an exuberant inflammatory response towards subclinical, incubating opportunistic pathogens, or previously diagnosed, as well as response towards other as yet undefined pathogens/antigens.<sup>116</sup>

There are no specific laboratory markers to differentiate HIV IRIS from OIs. The appearance of OIs within a rather loosely defined period of 8–12 weeks after initiation of ART should be identified as IRIS.

**Fig. 74.15:** Herpes zoster occurring as IRIS.

\*c+

\*d+

**Fig. 74.16:** Hypertrophic lichen planus occurring after starting treatment with ART, at CD4 Count: 571/mm<sup>3</sup>; suggestive of IRIS; (a) lesions over legs; (b) lesions over hands and forearms.

The frequently occurring cutaneous IRIS events include herpes zoster (Fig. 74.15) and herpes simplex infections, MAC infection, Hansen disease, Kaposi sarcoma, Reiter syndrome, sarcoidosis<sup>117,118</sup> foreign body granulomas, acne vulgaris, dyshidrosis, and lichen planus (Fig. 74.16 a&b). There is emergence of tropical skin diseases, such as leishmaniasis and leprosy, presenting in the context of immune recovery.<sup>119</sup>

Thorough screening for hidden/OIs should be done before starting ART to prevent development of IRIS. Unless IRIS is life threatening, there is usually no reason to stop ART. There are no clear guidelines for the management of severe IRIS; approaches

**Fig. 74.17:** A 17-year-old HIV-positive male with numerous molluscum contagiosum lesions.

**Fig. 74.18:** Herpes zoster in an HIV-positive child.

include temporarily stopping the ART until the patient has stabilized and using systemic corticosteroid therapy to reduce inflammation.

### MUCOCUTANEOUS MANIFESTATIONS IN CHILDREN

Mucocutaneous diseases are more frequent in HIV/AIDS-infected children than in the normal population. Majority of these cutaneous disorders have an infectious etiology like severe, persistent, and recurrent infection with *Streptococcus pneumoniae* and *H. influenzae*, and their frequency is related to

the degree of deterioration of the immune system. Some diseases commonly observed in adults are rare in children; neoplasms are an exception.<sup>120</sup>

Mucocutaneous manifestations were noted in 53% of the patient population studied, the most common lesions were infectious in nature (fungal 67% with oral candidiasis as the most frequent fungal infection; viral 29%, mostly molluscum contagiosum (Fig. 74.17) and herpes zoster lesions (Fig. 74.18); parasitic 5% and bacterial 2%), followed by epidermal hyperproliferative states (29%), which included seborrheic dermatitis, ichthyosis, and xerosis. Hypersensitivity rashes accounted for 9%, three cases secondary to TMP/SMX and one presumed to be secondary to HIV. Recurrent aphthous ulcers of unknown etiology were noted in 2 children. All patients with CD4 less than 500/ $\mu$ L had mucocutaneous disease. There was an increase in incidence of molluscum contagiosum, recurrent herpes zoster and ichthyosis in the more immunosuppressed group. These patients had more severe or recurrent disease that was recalcitrant to therapy and had multiple manifestations.<sup>121</sup>

### Conclusion

It is well-quoted that skin is the mirror which reflects many internal conditions and this is aptly applicable to HIV infection/AIDS. Mucocutaneous manifestations of HIV have diagnostic and prognostic significance.

Pre- and post-ART era have seen an enormous change in the way HIV/AIDS interacts with skin. On one hand, ART has got tremendous impact on dermatologic manifestations of AIDS, with the duration and severity decreasing in post-ART years; ART on the other hand has come up with its own challenges, like ADR and IRIS. The initial manifestations of both ADR and IRIS can be dermatologic, providing a dermatologist the opportunity for early diagnosis and prompt management.

In many chronic dermatologic conditions, immune system plays a significant role and hence the change in immunity due to HIV infection alters the picture of all these conditions. HIV dermatology is an evolving science which needs inputs from physicians, dermatologists and all those working for HIV care. Interaction between skin and HIV/AIDS should be carefully studied and its thorough knowledge and a know-how of its implications are imperative for all HIV and skin care physicians, particularly in settings where resources are scarce and clinical diagnosis holds the fort.

### Acknowledgement

We acknowledge Dr. Priyanka Singhal, postgraduate student, Department of Skin & VD, Medical College, Baroda for her invaluable contribution.

## Summary

- Dermatological diseases in HIV are a spectrum of inflammatory, infectious, and oncogenic disorders. They are in most of the situations diagnostic markers of HIV infection and opportunistic infections. They have specific prognostic significance independent of other markers.
- Langerhans cells in skin are CD4 bearing cells and their number as well as function is reduced in HIV. Moreover, being numerous in preputial skin, they are the prime targets of HIV.
- Mucocutaneous manifestations of HIV can be classified as infectious manifestations, non-infectious dermatoses, cutaneous adverse drug reactions (ADR) of ART, specific mucosal manifestations, hair manifestations, nail manifestations.
- Herpes simplex viral infection is one of the most common opportunistic infections in the HIV infected patients. HIV and HSV are co-transmitters of each other. HIV positive patients with HSV infection shed more HSV from genital mucosal tract even in absence of clinical herpes. HSV on the other hand perpetuates HIV disease progression. Herpes zoster presents atypically in a person infected with HIV where lesions can be hemorrhagic, crusted, and even disseminated (multi-dermatomal).
- Symptomatic HPV infection is only tip of the iceberg. Asymptomatic shedding is much more common in women with HIV/AIDS. Incidence of HPV infection does not decrease with ART and restoration of immune function. HPV causes various grades of squamous intraepithelial lesion, and invasive squamous cell carcinoma over cervix, anus, perineum, vulva, penis, oropharynx, and nail, more commonly in HIV infected than in HIV noninfected individuals. Invasive cervical cancer is aggressive in nature and is an AIDS defining condition.
- The clinical appearance of the lesions of cutaneous TB is not always characteristic and culture might be negative because skin lesions are typically paucibacillary. TB must always be suspected in a case of non-healing ulcer in an HIV positive patient, who is not responding to antibiotics and antiherpetic therapy.
- Oropharyngeal candidiasis is the most frequent opportunistic fungal infection in HIV positive patient.
- Pruritic papular eruptions are the most common cutaneous non-infectious manifestation of HIV. It is a marker of advanced HIV infection, occurring at CD4 T cell counts below 100–200/μL.
- Zidovudine is known to cause diffuse nail pigmentation as well as longitudinal or transverse hyperpigmented bands. All NNRTIs, especially nevirapine, can cause cutaneous ADR, which are mild to moderate in majority cases, but can be severe like SJS/TEN. Rash may also accompany hepatotoxicity. This might necessitate switch to efavirenz-based ART regimen. Protease inhibitors and stavudine can cause lipodystrophy syndrome leading to cosmetic disfigurement in AIDS patients.
- Paradoxical deterioration in the clinical status of HIV infected patients after initiation of ART, despite satisfactory control of viral replication and improvement in CD4 counts, can occur due to restoration of immune system and this phenomenon is known as **IRIS (immune reconstitution inflammatory syndrome)**. Thorough screening for hidden/opportunistic infections should be done before starting ART to prevent development of IRIS.

# Pulmonary Manifestations of HIV Disease

Resham Vasani • Ratnakar Kamath • J.K. Maniar

# 75

## Introduction

The lungs, along with the gastrointestinal tract (GIT), constitute the first site of interaction between environmental pathogens and the human body. The lungs are the principal targets of HIV infection, and the pulmonary macrophages play an important role in the pathogenesis of the acquired immunodeficiency syndrome (AIDS). They are known to be discrete target cells for human immunodeficiency virus (HIV), and compelling evidence is accumulating that alveolar macrophages (AMs) from HIV-infected patients behave as versatile secretory cells that, acting as antigen-presenting cells, release a great variety of cytokines. The secretory products of AMs, pivotal to their immune effects, may contribute to localized immune dysregulation as well as to primary lung damage and clinical disease. Pulmonary macrophages are also thought to facilitate retroviral spread by their direct infection, by presenting HIV antigens to uninfected T cells, and by secreting cytokines that transactivate HIV expression. Therefore, persons with HIV infection are at an increased risk for a wide spectrum of opportunistic pneumonias, neoplasms, and pulmonary pathologies<sup>1</sup> (Table 75.1).

Pulmonary disease is a major cause of illness and death in adults with HIV infection. The presentation and type of pulmonary involvement varies with the stage of the disease, geographical area and patient's socioeconomic status. Primary HIV infection may involve the lungs in the form of pneumonitis. As the disease progresses, approximately 70% of the HIV infected patients will have at least one respiratory episode during the course of the disease. Table 75.2 gives a list of pulmonary conditions that are commonly seen in HIV according to the CD4 counts.<sup>2</sup>

## Infectious Complications

### BACTERIAL INFECTIONS

Upper respiratory tract infections such as otitis media and sinusitis occur with increased frequency in HIV patients. Bacterial tracheitis and recurrent bacterial bronchitis often associated

**Table 75.1:** Spectrum of Respiratory Tract Complications of Patients with HIV Infection

<b>Bacterial pneumonias</b>
<i>Streptococcus pneumoniae</i> <i>Haemophilus influenzae</i> <i>Pseudomonas aeruginosa</i> <i>Staphylococcus aureus</i> <i>Moraxella catarrhalis</i> <i>Rhodococcus equi</i> <i>Nocardia asteroides</i>
<b>Mycobacterial infections</b>
<i>M. tuberculosis</i> <i>M. avium</i> complex (MAC) Other nontuberculous mycobacteria
<b>Fungal infections</b>
<i>Pneumocystis jiroveci</i> <i>Cryptococcus neoformans</i> <i>Histoplasma capsulatum</i> <i>Aspergillus fumigatus</i> <i>Coccidioides immitis</i> <i>Blastomyces dermatitidis</i>
<b>Protozoal infections</b>
<i>Strongyloides stercoralis</i> (metazoa) <i>Toxoplasma gondii</i>
<b>Viral infections</b>
<i>Cytomegalovirus</i> (CMV) <i>Adenovirus</i> <i>Herpes simplex</i>
<b>Malignancies</b>
Kaposi sarcoma Non-Hodgkin lymphoma, including primary effusion lymphoma Carcinoma of the lung
<b>Other disorders</b>
Sinusitis Bronchitis Bronchiectasis Emphysema Lymphocytic interstitial pneumonia Nonspecific interstitial pneumonia Cryptogenic organizing pneumonia Pulmonary hypertension Immune reconstitution inflammatory syndrome

**Table 75.2:** Spectrum of Pulmonary Diseases in HIV Infected Individuals as per the CD4 Count

CD4 count	Disease condition
<500 cells/ $\mu$ L	<ul style="list-style-type: none"> <li>• Sinusitis/mastoiditis/otitis</li> <li>• Bronchitis</li> <li>• Bacterial pneumonia</li> <li>• Pulmonary tuberculosis</li> </ul>
<200 cells/ $\mu$ L	<ul style="list-style-type: none"> <li>• <i>Pneumocystis jiroveci</i> pneumonia</li> <li>• Kaposi sarcoma</li> <li>• Disseminated tuberculosis</li> </ul>
<100 cells/ $\mu$ L	<ul style="list-style-type: none"> <li>• Disseminated MAC</li> <li>• Cytomegalovirus disease</li> <li>• Disseminated fungal infection</li> </ul>

with bronchiectasis have also been reported in HIV infected individuals.

### Bacterial Pneumonias

The incidence of bacterial community acquired pneumonia (CAP) is increased in HIV-infected individuals because the depleted CD4 helper T cells lead to diminished humoral immunity. Hence, recurrent bacterial pneumonia is an AIDS defining condition.<sup>3</sup> Bacterial pneumonias may be the first manifestation of underlying HIV infection and thus presence of HIV infection should be considered in any patient presenting with bacterial pneumonias especially if the individual has no other risk factor for bacterial pneumonias or if pneumonia is nonresolving. Similar to persons without HIV infection, *Streptococcus pneumoniae* and *Haemophilus* species are the most frequently identified causes of bacterial CAP.<sup>4</sup> *Pseudomonas aeruginosa* and *Staphylococcus aureus* are also more frequently reported.

Risk factors for *Pseudomonas* include advanced HIV/AIDS (i.e., CD4 cell count at or below 50 cells/ $\mu$ L), underlying lung disease (bronchiectasis), neutropenia, corticosteroid therapy, and severe malnutrition. Risk factors for *S. aureus* include recent viral or influenza infection, use of injection/inhalational drugs, cigarette smoking, and previous *Pneumocystis jiroveci* pneumonia (PCP). Atypical pathogens such as *Legionella pneumophila*, *Mycoplasma pneumoniae*, and *Chlamydia pneumoniae* species are less frequent causes of pneumonia, and are encountered with similar frequency as among those without HIV.

*Rhodococcus equi* is a gram-positive, facultative, intracellular coccobacillus and is a cause of acute or insidious pulmonary infections (often cavitating pneumonia), bacteremia, and disseminated disease in patients with advanced HIV. Also, nocardiosis in AIDS is characterized by cavitary pulmonary infiltrates and brain abscess (Fig. 75.1).

### Clinical Presentation

The clinical presentation of HIV-associated bacterial pneumonia is similar to that in persons without HIV infection. They typically present with the acute onset (3–5 days) of fever, chills/rigors, chest

**Fig. 75.1:** Nocardiosis—Lung abscess.

pain, dyspnea, and productive cough with purulent sputum. Lung examination reveals evidence of consolidation and occasionally pleural effusion.

### Diagnosis

Laboratory testing is usually notable for an elevated white blood cell count, often with a predominance of polymorphonuclear leukocytes (PMNs).

The radiographic presentation is similar to usual CAP (Fig. 75.2a, b). Most persons with *S. pneumoniae* or *Haemophilus pneumoniae* present with unilateral, focal, segmental, or lobar consolidation, occasionally accompanied by pleural effusion. Focal airspace disease, ranging from patchy bronchopneumonia to segmental/lobar consolidation with air bronchograms may also be noted.

Diagnostic evaluation of suspected bacterial pneumonia includes a pretreatment expectorated sputum specimen for Gram stain and culture, two blood cultures, and thoracentesis if pleural effusion is present. Arterial blood gases typically reveal an increased alveolar-arterial (A-a) gradient. Since *R. equi* and *N. asteroides* are weakly acid fast, Ziehl–Neelsen staining should also be done to rule out these organism as well as *Mycobacterium tuberculosis*.

### Treatment

In patients with uncomplicated pneumonia without respiratory distress and normal oxygen saturation, treatment with amoxicillin-clavulanate and an additional second-generation cephalosporin should be instituted on an outpatient basis. Alternatively, a regimen consisting of macrolide, azalide, or tetracycline may be used. Seriously ill patients should receive a third or fourth-generation cephalosporin (e.g., ceftriaxone and cefepime, respectively) or a fluoroquinolone (e.g., levofloxacin). If *Legionella* is suspected, then the initial antibiotic should be clarithromycin, azithromycin, or a fluoroquinolone.

\*c+

\*d+

**Fig. 75.2 a,b:** Bacterial pneumonia.

### Prevention

Persons with HIV infection who have a CD4 cell count greater than 200 cells/ $\mu$ L should be given the 23-valent polysaccharide pneumococcal vaccine.<sup>5</sup> Since the duration of the protective effect of vaccination is unknown, revaccination every 5 years should be considered. Persons with a CD4 cell count less than 200 cells/ $\mu$ L can also be offered the vaccine. Although its efficacy may be lessened in those with advanced immunosuppression, observational studies suggest that the vaccine may still decrease the risk for pneumonia in this population.<sup>6,7</sup> If antiretroviral therapy is to be initiated, the vaccine can be given after the CD4 cell count rises above 200 cells/ $\mu$ L.

Other measures that may decrease the incidence of pneumonia among HIV-infected persons include the administration of the

inactivated influenza vaccine annually before influenza season. However, in a resource-limited setting, vaccination is not a feasible option. Trimethoprim-sulfamethoxazole (TMP-SMX), administered daily for PCP prophylaxis and azithromycin/clarithromycin administered for *Mycobacterium avium* complex prophylaxis can reduce the frequency of bacterial pneumonia. The efforts to improve smoking cessation could lead to substantial decreases in bacterial pneumonias.

### Tuberculosis

About one third of the world's population has latent tuberculosis. Most new cases occur in the most populated nations of India and China, but the highest rates of disease are seen in sub-Saharan Africa. *Mycobacterium tuberculosis* is the single most commonly seen coinfection among HIV infected persons in South and South-East Asia, especially India.<sup>8</sup>

HIV influences tuberculosis (TB) by causing the progressive loss of cell mediated immunity by reduction in the CD4 levels, impaired T cell proliferation, and reduced cytokine elaboration in response to mycobacterial antigen challenge. This enhances the risk of acquiring a new/active infection or reactivation of latent disease. Reinfection with a second distinct strain may also occur, in spite of completing the recommended treatment regimen.

Conversely, TB influences the HIV infection by activation of CD4 lymphocytes, which enhances their susceptibility to HIV. The cytokines elaborated by the lymphocytes and macrophages in patients with tuberculosis and HIV, in particular TNF- $\alpha$  and IL-1 upregulate HIV expression.

### Clinical Features

The diagnosis should be suspected not only in patients with pulmonary symptoms but also in those with constitutional symptoms like weight loss, fever of unknown origin and malaise. Tuberculosis can occur at any stage of HIV disease and at any CD4 cell count,<sup>9</sup> although the median CD4 cell counts range from 150 to 300 cells/ $\mu$ L.

In patients with higher CD4 counts ( $>300$  cells/ $\mu$ L) TB is more typically a reactivation disease, involving lungs predominantly with upper lobe infiltrates with or without cavitations and a positive Tuberculin test.<sup>10</sup> Symptoms include productive cough, fever, night sweats, weight loss, and occasionally pleuritic chest pain, hemoptysis, or dyspnea.

In patients with lower CD4 ( $<200$  cells/ $\mu$ L) counts, there is<sup>11</sup>:

- An increased likelihood of dissemination.
- Clinical features mimic *Pneumocystis jiroveci* pneumonia (PCP) with diffuse interstitial infiltrates or alveolar infiltrates.
- Extrapulmonary involvement of the central nervous system (CNS), the reticulo-endothelial system (RES) viz the liver, spleen, lymph node, bone marrow, and bone (vertebral bodies) is more common. Uncommon sites include the urinary tract, pericardium, skin, GIT, and the reproductive system.
- Atypical manifestations include primary progressive lung disease with acute or subacute fever, cough, breathlessness,

and decreased oxygen saturation accompanied by hilar lymphadenopathy and lower lobe, hilar, or interstitial infiltrates. This presentation is difficult to differentiate from other OIs and is mostly a new infection in a seriously immunosuppressed individual.

### Diagnosis

1. Acid fast smears of respiratory secretions or tissue samples are useful. Sensitivity of sputum AFB smear and culture in HIV infected patients is similar to the sensitivity in the overall population and depends on the degree of immunosuppression. However, only two-thirds to three-quarters of the HIV infected patients with pulmonary tuberculosis will have a positive AFB smear.

According to the WHO 2007 guidelines, pulmonary TB can be diagnosed if – one acid fast bacillus (AFB) is seen in at least one sputum sample.<sup>12</sup> Smear negative TB can be diagnosed if the following criteria are met:

- At least two sputum samples are negative for AFB.
- Radiographic abnormalities are consistent with active TB.
- Strong clinical evidence of TB.
- Decision by clinician to treat with full course of antituberculosis chemotherapy.

All patients diagnosed with smear negative pulmonary TB should have at least one sample sent for liquid media culture. A negative culture does not rule out TB but a positive culture confirms the diagnosis and conversion of the culture from positive to negative on follow-up suggests that the patient is responding to treatment.

2. Radiographic findings that suggest active HIV associated TB are:
  - Asymptomatic air space opacification.
  - Miliary or micronodular infiltrates (Fig. 75.3 a,b).
  - Cavitation which may be subtle (Fig. 75.4 a,b).
  - Pleural effusion (Fig. 75.5 a,b).
  - Mediastinal or hilar lymphadenopathy (Fig. 75.6).
  - Scattered soft pulmonary nodules (Fig. 75.7).
  - Increased cardiothoracic ratio suggestive of pericardial effusion.
  - Normal radiograph.
3. Molecular techniques include Roche Amplicor PCR and Gen-Probe Amplified PCR for *Mycobacterium tuberculosis*. Use of PCR is important in detecting the organism in areas like cerebrospinal fluid where it is not normally seen. Specimen for the test can be obtained by sputum collection, bronchoalveolar lavage, bone marrow aspirate and biopsy, fine needle aspiration cytology of the nodes and other sites.
4. Tuberculin skin test: The sensitivity of tuberculin skin test declines as CD4 counts fall. But even in advanced disease almost half of the patients with active tuberculosis will have a positive PPD. The test is however, done using 5 tuberculin unit (TU) and is considered positive when the induration is  $\geq 5$  mm. Among HIV infected patients with a

\*c+

\*d+

**Fig. 75.3a,b:** Miliary tuberculosis.

positive tuberculin test (PPD), the risk of developing active tuberculosis is 8–10% per year.<sup>13</sup>

### Treatment

The therapy for drug susceptible tuberculosis is generally believed to be as effective in the HIV infected patient as it is in the general population.<sup>14,15</sup> Isoniazid (INH) or Rifampicin are the most powerful bactericidal drugs. Pyrazinamide is bactericidal against tubercle bacilli in an acidic environment in macrophages. Streptomycin is bactericidal against rapidly multiplying bacilli.

The induction phase of 2 months of Isoniazid, Rifampicin, Pyrazinamide, and Ethambutol causes rapid killing of mycobacteria and decreases infectivity. The continuation phase of 4 months consisting of Isoniazid and Rifampicin causes sterilization and prevents relapses.

\*c+

\*d+

**Fig. 75.4a,b:** Pulmonary tuberculosis with cavity.

**Relationship between Antiretroviral Treatment (ART) and Antituberculosis Therapy (ATT)** Rifampicin based antituberculosis treatment can be given with NRTI and Efavirenz (EFV), but rifampicin interacts with protease inhibitors (PI) and nevirapine (NVP). Mortality is high in tuberculosis patients with low CD4 counts (<100 cells/mL) and consideration should be given to initiating ART as soon as antituberculosis drugs are tolerated (within 2 weeks).<sup>16</sup> If the CD4 counts are between 100 and 200 cell/mL, defer ART for the first 8 weeks of antituberculosis treatment. If the CD4 counts are between 200 and 350 cells/mL, defer ART until after completion of antituberculosis treatment.

**Fig. 75.5a:** Encysted pleural effusion.

**Fig. 75.5b:** Pleural effusion due to tuberculosis.

**Fig. 75.6:** Mediastinal TB nodes.

**Fig. 75.7:** Pulmonary infiltrate in tuberculosis.

### Multidrug-Resistant Tuberculosis (MDR-TB)<sup>17</sup> and Extensively Drug-Resistant TB (XDR-TB)

MDR-TB is defined as resistance to at least rifampicin and isoniazid, while XDR-TB is defined as resistance to at least rifampicin and isoniazid of the first-line drugs, and resistance to any fluoroquinolones, and any one of the three injectable second-line drugs (capreomycin, kanamycin, amikacin). MDR and XDR tuberculosis commonly occur due to inadequate and/or inappropriate application of DOTS. Preventive measures include undertaking treatment of MDR and XDR tuberculosis only in select institutions with experience, expertise, and availability of required diagnostic and treatment facilities. The fluoroquinolones group of drugs are not recommended as first-line anti-TB drugs and their use should only be restricted to confirmed MDR-TB cases.

MDR tuberculosis should be suspected in:

- Retreatment patients who remain sputum smear positive after 3 months of intensive treatment.
- Retreatment failure and defaulter cases.
- Close contacts of MDR-TB cases.
- Chronic cases of TB.

The rate of cure of MDR tuberculosis is less than 50% in HIV negative patients. For this reason initial empirical treatment of AIDS patients with suspected MDR tuberculosis should be with first-line drugs (isoniazid, rifampicin, ethambutol, pyrazinamide, streptomycin) with or without fluoroquinolones depending upon the local patterns of resistance.

Treatment should include at least three drugs to which the organism is sensitive or not previously administered; and should be continued for at least 2 years or 12 months beyond sputum-culture conversion.<sup>13</sup> Sputum smears should be done

every month, while culture and X-rays should be repeated after 8 weeks when both microbiologic and radiographic improvement is evident (Fig. 75.8). If cultures are still positive after 2 months of treatment, isolation and drug sensitivity should be repeated and the treatment regimen re-evaluated.

Drugs used in the treatment of tuberculosis are enumerated in Table 75.3.<sup>11</sup>

### Prophylaxis of Tuberculosis<sup>10</sup>

WHO recommends giving preventive therapy to all HIV infected patients in countries with high TB burdens if

**Fig. 75.8:** Multidrug-resistant tuberculosis.

**Table 75.3:** Drugs Used in the Treatment of Tuberculosis

<b>First-line oral ATT</b>	Isoniazid Rifampicin Pyrazinamide Ethambutol
<b>Injectable antituberculosis agents</b>	Amikacin Kanamycin Capreomycin Viomycin
<b>Fluoroquinolones</b>	Ciprofloxacin Ofloxacin Levofloxacin Moxifloxacin Gatifloxacin
<b>Oral bacteriostatic second-line antituberculous agents</b>	Ethionamide Prothionamide Cycloserine Terizidone PAS Thiacetazone
<b>Antituberculous therapy with unclear efficacy (not recommended for routine use in MDR-TB)</b>	Clofazimine Amoxicillin-clavulanic acid Clarithromycin Linezolid

**Fig. 75.9:** Reactive Mantoux test—latent tuberculosis.

tuberculin skin testing cannot be done (Fig. 75.9). Isoniazid at a dose of 300 mg daily given for 12 months is the best studied regimen in HIV infection. Pyridoxine 25–50 mg daily should be prescribed to prevent INH induced peripheral neuropathy. A shorter regimen of 6 months has been rejected because of poor protective efficacy.

### **Mycobacterium Avium Complex (MAC) Disease**

This entity comprises *M. avium*, *M. InterCellulare*, and other poorly characterized strains not classified as either. It is one of the commonest OIs in the United States and other developed countries. These organisms are ubiquitous in the environment in both soil and water. Infection with this and other nontuberculous mycobacteria occurs when the CD4 count is  $0.1 \times 10^9/L$ .

Typically patients present with disseminated multiorgan involvement characterized by fever, night sweats, weight loss, fatigue, diarrhea, and abdominal pain. Laboratory abnormalities include severe anemia and abnormal liver function tests, especially raised alkaline phosphatase levels. Clinical findings include hepatomegaly, splenomegaly, and intra-abdominal lymphadenopathy. Less commonly, pneumonitis, pericarditis, osteomyelitis, skin and soft tissue abscesses, or CNS involvement is seen. Pulmonary disease without dissemination is uncommon in patients with HIV infection although rarely localized infection of lung is encountered with cavitating lung infiltrates.

The diagnosis is made by growth of MAC on culture of blood or involved tissue. A positive AFB smear is nonspecific without culture and species identification. The finding of two consecutive sputum samples positive for *Mycobacterium avium* complex (MAC) is highly suggestive of this infection. Cultures may take

2 weeks to be positive. The fastest technique with maximum yield for culture combines radiometric detection in liquid media with DNA probe identification.

The infection is resistant to first-line antituberculosis therapy and, like tuberculosis, requires combination therapy with at least three active drugs. Therapy consists of a macrolide usually clarithromycin (500 mg bid) or azithromycin (500 mg or 1 g daily) with ethambutol. Some elect to add a third from rifabutin/rifapentine, ciprofloxacin, or amikacin in patients with extensive disease. Therapy has to be continued life-long to prevent relapse unless potent ART is instituted. If CD4 T cell counts increase and sustain above 100 cells/ $\mu L$  after ART, discontinuation of therapy is possible after completion of 12 months. Primary prophylaxis for MAC is indicated in HIV infection and CD4 T cell counts less than 50 cells/ $\mu L$ .

## **FUNGAL INFECTIONS**

### **Pneumocystis Jiroveci Pneumonia (PCP)**

#### **Etiology**

*Pneumocystis jiroveci* (*Pneumocystis carinii*) considered as protozoan for long time has now been placed in fungal kingdom with proximity to ascomycetes based on phylogenetic analysis of rRNA sequences. This fungus predominantly occurs in two forms traditionally called as 'cystic form' (cysts) and 'trophic forms' (trophozoites). Cystic form (considered as sporangium) is thick-walled, measures about 5–8  $\mu m$  in diameter and contains daughter cells (spores/endospores), whereas the trophic form (considered as yeast) is small (2–5  $\mu m$ ), thin-walled and pleomorphic. The third, precyst form is now known as intermediate form.

#### **Susceptibility**

Since PCP has also been found to develop in nonimmunocompromised persons, the majority before the age of 13 years, it has led to the suggestion that PCP is caused by the reactivation of latent infection. The infection occurs once the patient's resistance is sufficiently impaired. In HIV patients CD4 counts of less than 200/ $\mu L$  considerably increase the risk of developing PCP.<sup>2</sup> The transient but profound fall in the CD4 T-cell counts in patients at the initial or primary stage of seroconversion may also result in PCP.

#### **Pathophysiology**

The *P. jiroveci* trophozoites bind to the alveolar epithelial cells leading to the destruction of the type 1 and subsequent proliferation of type 2 pneumocytes.<sup>2</sup> This leads to the disruption of the epithelial barrier leading to the increased capillary membrane permeability and hence the accumulation of foamy, proteinaceous eosinophilic exudate containing cellular debris, surfactant, and cysts of *P. jiroveci* in the alveolar space; along with inflammatory infiltrate in the interstitium. The increased phospholipase activity leads to the degradation of the surfactant. These events cause the physiological shunting and decreased lung compliance precipitating hypoxia.

### Clinical Features

The presentation is subacute over 2–4 weeks, with the common clinical features including night sweats, low grade fever, dry cough, and dyspnea that progresses from mild breathlessness on physical exertion to tachypnea at rest. Weight loss and retrosternal chest pain are rarely encountered. One third of the patients may present with sputum production and chest pain.

Physical examination of the chest is unremarkable in approximately 50% of the patients. Inspiratory crackles are the most common abnormal finding on lung examination. Typically the patient appears disproportionately symptomatic and distressed, when compared with the clinical signs and examination findings.

The severity of disease is classified based on the room air arterial blood gas (ABG) and difference between alveolar to arterial oxygen pressures ( $D_{A-a}O_2$ ). The clinical significance of this classification is to define the management plan depending upon the severity. Mild disease is defined as a  $PO_2 > 70$  mmHg and a  $D_{A-a}O_2 < 35$  mmHg while the severe disease has a  $D_{A-a}O_2 > 45$  mmHg. The severity worsens when the  $PO_2$  decreases and  $D_{A-a}O_2$  increases with progressive disease.

### Investigations

Sometimes the diagnosis of PCP becomes so obvious on clinical presentation and examination that treatment may be started empirically. There is evidence that such an empirical approach is not associated with any worse outcome.

### Diagnosis

Diagnosis requires demonstration of the organism in tissue or secretions.

**Microbiological Investigations** Induced sputum analysis, using 3% saline, has been claimed to be very sensitive (up to 90%) by some groups, but its usefulness is highly dependent on procedures being meticulously followed from bedside to laboratory. Sputum for *P. jiroveci* can be examined by doing a direct immunofluorescence (IF) test which employs anti *P. jiroveci* antibodies resulting in significantly improved sensitivity compared with standard staining methods. If sputum induction and examination is negative, then the patient should undergo fiber-optic bronchoscopy (FOB) and bronchoalveolar lavage (BAL). This procedure is more sensitive when performed in both the right upper lobe (RUL) and right middle lobe (RML). If BAL is also negative, then PCP is very unlikely and a lung biopsy obtained through transbronchial, thoracoscopic, or open technique is required to confirm or refute the diagnosis. Examination of induced sputum and even BAL may be negative if the patient has used pentamidine prophylaxis.

Other staining methods used to visualize the cysts or trophozoites of *P. jiroveci* include:

- Silver methenamine.

- Modified Giemsa
- Toluidine blue

Polymerase chain reaction (PCR) can be used to detect DNA in specimens such as induced sputum or BAL fluid.

**Radiological Tests** Chest radiographs: Patients with early PCP may sometimes develop mild symptoms before the appearance of any definite chest radiographic abnormality. Hence, a normal chest film does not rule out PCP. The most typical early abnormality found in PCP is that of bilateral, hazy, ground glass, perihilar infiltrates with sparing of the lung peripheries. The most common pattern in established disease is bilateral diffuse interstitial infiltrates. As the disease progresses, more homogenous consolidation with air bronchograms may develop. Ultimately the lungs may become massively consolidated and seemingly airless (Fig. 75.10).

Less common X-ray findings are<sup>18,19</sup>:

- Focal infiltrates.
- Nodular appearances with cavitation. Selective upper lobe involvement that may mimic mycobacterial disease.
- Subpleural cyst disease sometimes leading to spontaneous pneumothorax.
- Hilar lymphadenopathy.
- Pleural effusion and changes consistent with bronchiectasis.

High resolution computed tomography (HRCT) is useful in excluding PCP when history is suspicious but the chest radiograph remains normal. Such scans show bilateral ground glass opacification sometimes sparing subpleural lung tissue. (Fig. 75.11).

If radiography is inconclusive but clinical suspicion is strong, then a gallium scan can be performed. A diffuse uptake is consistent with PCP.

**Nonmicrobiological Investigations** Non-microbiological investigations include the following:

- CD4 T-cell count – invariably less than 200 cells/ $\mu$ L.
- Serum lactate dehydrogenase is increased in approximately 93% patients, specifically the LDH-3 fraction.<sup>20</sup> A serum LDH > 450 IU/L is strongly predictive and prognostic in PCP.

**Fig. 75.10:** Ground glass appearance—*Pneumocystis jiroveci* pneumonia.

**Fig. 75.11:** Ground glass appearance—*Pneumocystis jirovecii* pneumonia (high resolution computerized tomography scan).

- Decreased diffusion capacity of the lung for carbon monoxide (DLCO).<sup>21</sup>
- Monitoring of oxygen saturation by pulse oximetry. This is also used to screen patients with normal or minimally abnormal chest radiographs and resting saturations, in which case a failure to desaturate with exercise effectively rules out PCP.
- Anemia as a result of underlying disease or as a result of the treatment.
- Total leukocyte count may be normal or low.
- Hypoalbuminemia is not uncommon.

### Treatment

Mild disease may be treated on an outpatient (OPD) basis, but patients with moderate/severe disease should be hospitalized and treated. Adjunctive steroid therapy should be considered in addition to oxygen supplementation in patients with poor gas exchange. A transient worsening of symptoms is expected in all patients after initiation of treatment. Therapy is generally continued for 3 weeks. In mild disease, it may be discontinued after 2 weeks, but prophylaxis for recurrence is mandatory and should be instituted in all patients after completion of active treatment. The treatment is summarized in Table 75.4.

**Adjunctive Corticosteroids** High-dose corticosteroids given as adjuvant to conventional antimicrobial treatment in patients with moderate to severe PCP can be expected to significantly reduce the chances of deterioration and death.<sup>22</sup> The regimen is 40 mg bid for 5 days, then 20 mg bid for 5 days, then 20 mg once daily till therapy is complete.

Monitoring the response to treatment is extremely important, OPD follow-up is recommended twice a week. Both the patient's clinical improvement and compliance should be recorded. In moderate/severe disease, repeat ABGs should be performed to assess oxygenation status. An early transient deterioration in oxygen saturation is expected in approximately 50% of the treated patients. It improves by the end of the first week or with steroid therapy. In case the deterioration persists after 7 days, therapeutic failure should be considered and second line of drug therapy should be started.

**Table 75.4:** Treatment of *Pneumocystis jirovecii* Pneumonia

Treatment	Drug	Dose/route	Comments	Side effects
First line	Co-trimoxazole (Trimethoprim sulfamethoxazole)	15/75 mg/kg/d IV or oral	Any grade of pneumonia. Inexpensive, readily available. Acts also against other pathogens	Rash GI intolerance Bone marrow toxicity Avoid in G6PD deficiency
Second line	Pentamidine isethionate	4 mg/kg/d slow IV infusion	Severe PCP	Hypotension Hypoglycemia Nephrotoxicity Hepatotoxicity Pancreatitis Arrhythmias
Second line	Dapsone Trimethoprim	Dapsone 100 mg (oral) & Trimethoprim 300 mg (oral)	Mild to moderate PCP	Bone marrow toxicity Rash GI disturbances
Third line	Clindamycin Primaquine	Clindamycin 450–600 mg 3x/d (oral) & Primaquine 15 mg/d or 30 mg base (oral)	Mild to moderate PCP	Maculopapular rash <i>C. difficile</i> diarrhea Avoid in G6PD deficiency
Fourth line	Atovaquone	750 mg 2x/d	Mild to moderate PCP	Rash GI intolerance Poor enteric absorption
Fourth line	Trimetrexate with Leucovorin	IV Trimetrexate 45 mg/m <sup>2</sup> once daily; IV or oral calcium folinate 20 mg/m <sup>2</sup> four times daily. The dose may be doubled to 40 mg/m <sup>2</sup> if toxicity occurs. Leucovorin should be continued for 3 days after trimetrexate is discontinued	Mild to moderate PCP	Thrombocytopenia Neutropenia Oral and GI ulceration Hepatic and renal dysfunction Peripheral neuropathy

**Treatment for Respiratory Failure** Respiratory failure may develop despite adequate treatment and is treated along the usual lines with same indications for mechanical ventilation as for any respiratory failure. Adverse reactions to drugs occur in 50–100% of HIV infected patients. If an allergic reaction is moderate/severe or the patient cannot tolerate other effective medications to *Pneumocystis jiroveci* pneumonia, desensitization to trimethoprim-sulfamethoxazole is recommended.<sup>23,24</sup>

### Prophylaxis against *Pneumocystis Jiroveci* Pneumonia

Primary prophylaxis is administered to prevent pneumonia in predisposed individuals, while secondary prophylaxis given to prevent relapse after successful treatment.

Current recommendations for prophylaxis include<sup>25</sup>:

- Patients with CD4 count less than 200 cells/ $\mu$ L are 9 times more likely to develop PCP within 6 months than individuals on therapy.
- CD4/TLC ratio is less than 1:5.
- Oropharyngeal thrush or unexplained fever for 2 or more weeks even if the cells exceed the value of above.
- AIDS defining diagnosis such as Kaposi sarcoma, cerebral toxoplasmosis, or cryptococcal meningitis.
- Recovery from previous episode of PCP.

Drugs used in prophylaxis of *Pneumocystis jiroveci* pneumonia are enumerated in Table 75.5.

### Other Fungal Infections

Other fungal infections include cryptococcosis, histoplasmosis, blastomycosis, aspergillosis, sporotrichosis, penicilliosis, and coccidioidomycosis.

**Table 75.5:** Drugs Used in Prophylaxis of *Pneumocystis jiroveci* Pneumonia

Prophylaxis	Drug	Dosage	Side effects
First line	Co-trimoxazole 80/400 mg	2 tablets/d	Rash GI intolerance Bone marrow toxicity
Alternatives	Co-trimoxazole 80/400 mg Co-trimoxazole 80/400 mg	2 tablets 3x/wk 1 tablet/d	
Second line	Dapsone	100 mg/d	Rash GIT disturbance Hemolytic anemia in G6PD deficiency.
Third line	Atovaquone	750 mg 2x/d	Rash Deranged liver function
Fourth line	Nebulized pentamidine	300 mg/mo via jet nebulizer	Bronchospasm Metallic taste Renal impairment Hypoglycemia Pancreatitis

Cryptococcal pneumonia usually presents as a part of a disseminated infection with meningitis and fungemia. Pulmonary involvement occurs in a third, however, primary lung disease is rare. Pleurisy is the common presentation (40%). Chest radiograph patterns include large nodules, nonconfluent opacification, diffuse interstitial infiltrates, and cavitation. Enlarged nodes or pleural effusions are uncommon. Diagnosis includes the demonstration of cryptococcal antigen in serum which has more than 90% sensitivity and specificity for the presence of disseminated disease in AIDS patients. The disadvantage of this test is that it is not specific for site of involvement. Definitive diagnosis requires isolation of the organism from a respiratory source (BAL, sputum, lung tissue, or pleural fluid). Amphotericin B (alone or in combination with flucytosine) is the drug of choice. A total dose of at least 2–2.5 g of amphotericin B has to be administered before starting maintenance treatment. Patients with isolated pulmonary disease may be given 400 mg of fluconazole daily for life.

Invasive aspergillosis is not an AIDS-defining illness and is generally not seen in patients with AIDS in the absence of neutropenia or administration of glucocorticoids. The pulmonary disease may be parenchymal in the form of cavitary predominantly upper lobe disease or focal bilateral upper lobe infiltrates or in the form of obstructive bronchial aspergillosis or an ulcerative tracheobronchitis (Fig. 75.12 a,b,c,d). Diagnosis of pulmonary aspergillosis requires the documentation of invasion on a biopsy specimen. Treatment is with amphotericin B.

Primary pulmonary infection of the lung may be seen with histoplasmosis. The most common pulmonary manifestation of histoplasmosis however, is in the setting of disseminated disease presumably due to reactivation. Respiratory involvement typically presents with fever, fatigue, weight loss, cough, and dyspnea. Other manifestations include a nodular skin rash, oral ulcers, and diffuse micronodular pattern on chest radiograph (Fig. 75.13 a,b). The drug of choice is amphotericin B with itraconazole being a less toxic and effective alternative, which can also be used as a maintenance therapy.

**Fig. 75.12a:** *Aspergillus niger*—microscopic appearance.

**Fig. 75.12b:** Chest radiograph in aspergillosis.

**Fig. 75.12c:** Growth of Aspergillus in culture.

**Fig. 75.12d:** Cavity in pulmonary aspergillosis.

## PARASITIC INFECTIONS

*Toxoplasma gondii* is the most frequent parasitic pneumonia seen in persons with HIV infection who are not on ART or primary

**Fig. 75.13a:** Histoplasmosis skin eruptions.

**Fig. 75.13b:** Histoplasmosis—pulmonary involvement.

prophylaxis. The disease represents reactivation of latent infection, rather than new infection, and occurs in advanced AIDS (CD4 counts  $<100/\mu\text{L}$ ).

*Toxoplasma gondii* encephalitis is a well-recognized complication of advanced HIV disease and is an AIDS-defining condition. Although toxoplasmosis is the most common cause of focal brain abscesses in HIV-infected persons, pulmonary involvement is uncommon. Pulmonary disease may occur in persons with CNS involvement or disseminated disease or with isolated pulmonary involvement. Pulmonary toxoplasmosis characteristically presents with cough that is nonproductive, dyspnea, and fever. It may be clinically indistinguishable from PCP. Occasionally, disseminated toxoplasmosis may present with acute respiratory failure. Physical examination of the chest may be normal or may reveal crackles. Focal neurologic findings are common.

The chest radiograph usually reveals bilateral infiltrates, either fine reticulonodular infiltrates indistinguishable from PCP or a coarser nodular pattern similar to that seen with tuberculosis or fungal pneumonias. A positive toxoplasma IgG antibody and the presence of toxoplasma in BAL help in the diagnosis. Sulfadiazine plus pyrimethamine is the first-line recommended treatment

for *Toxoplasma* infection.<sup>5</sup> Leucovorin is coadministered with pyrimethamine to reduce the occurrence of hematologic toxicities from pyrimethamine. Clindamycin plus pyrimethamine (and leucovorin) and trimethoprim-sulfamethoxazole (TMP-SMX) are the main alternatives. Mortality is high (approximately 35%), in spite of treatment.

Prevention is indicated in people with CD4 cell count below 100 cells/ $\mu$ L by administration of TMP-SMX.<sup>5</sup> Dapsone plus pyrimethamine (and leucovorin) and atovaquone with or without pyrimethamine (and leucovorin) are recommended for persons who cannot tolerate TMP-SMX.

## VIRAL INFECTIONS

## Herpes Viruses

HIV infection is characterized by infections with the herpes group of viral infections. Complications usually manifest in the extrapulmonary sites.

## CMV Infections

CMV infection occurs in 100% of gay men with HIV infection and to a lesser extent in other risk groups. It usually occurs after significant immunosuppression (CD4 count less than 100 cells/ $\mu$ L). The most common manifestation of CMV disease is retinitis, although lungs, central nervous system, colon may also be involved. Pneumonitis is mainly subclinical, but clinical disease usually presents with nonspecific symptoms (Fig. 75.14).

Diagnosis is via BAL or sputum induction which reveals typical inclusion bodies in smears fixed with Giemsa or hematoxylin-eosin in 20–30% cases.

Treatment with nucleoside analogues ganciclovir, foscarnet, or cidofovir should be considered in symptomatic patients if there is documented CMV pulmonary involvement in absence of other pathogens.

**Fig. 75.14:** Cytomegalovirus pneumonia.

## Herpes Simplex Virus and Varicella Zoster Virus Pneumonitis

Herpes simplex virus (HSV) pneumonitis is very rare, and occurs as a result of either disseminated or tracheobronchial disease. Varicella zoster virus (VZV) pneumonitis is a particularly severe complication of HIV infection in children and is usually accompanied by vesicular rash. Herpes zoster is not usually accompanied by pneumonitis in adults. Diagnosis is by viral culture from appropriate respiratory secretions and histopathology. Treatment is with IV acyclovir.

## ■ Noninfectious Complications

## KAPOSI SARCOMA

Kaposi sarcoma (KS) is caused by HHV8. It is the most common malignancy associated with HIV infection. It occurs in 6–20% of HIV infected homosexual or bisexual men.<sup>26,27</sup> Lung involvement is detected in 20–40% of these patients and is usually accompanied by skin and mucosal lesions, but has been described in isolation. The malignancy may obstruct the airways directly or indirectly due to pulmonary edema as a result of lymphatic obstruction. It may cause large effusions, lung consolidation and hemorrhage.

Pulmonary involvement with Kaposi sarcoma is generally with shortness of breath, especially on exertion and cough. Stridor and hemoptysis in a patient with diagnosed mucocutaneous KS is pathognomonic of pulmonary involvement. Associated OIs are very common and complicate the clinical picture.

Radiographic appearances can be as the focal infiltrative lesions, pleural effusion or mediastinal adenopathy. The chest X-ray characteristically shows bilateral lower lobe infiltrates that obscure the margins of the mediastinum and diaphragm. Red or purple lesions can be seen endobronchially during FOB. Biopsy is usually avoided because lesions are highly vascular. Treatment with cytotoxic chemotherapy is relatively unsuccessful, and palliative treatment is required for bleeding or obstructive lesions. Highly active antiretroviral therapy helps in resolution of lesions. Median survival in HIV positive patients with extensive KS is between 2 and 10 months.

## Non-Hodgkin Lymphoma (NHL)

Patients with HIV-related NHL present with symptoms of night sweats, fever, and weight loss; usually when CD4 counts are less than 100 cells/ $\mu$ L. Disease is often extranodal, although patients may have an enlarging mass on a chest radiograph (Fig. 75.15 a,b).

## OTHER MALIGNANT CONDITIONS

Primary lung tumors are occasionally associated with HIV infection.<sup>28</sup> Other tumors such as Hodgkin lymphoma, multiple myeloma, and metastases from brain tumors and seminomas were unequivocally associated with HIV infection.

**Fig. 75.15a:** Enlarging mediastinal mass.

**Fig. 75.15b:** Enlarging mediastinal mass in chest radiograph.

## INTERSTITIAL PNEUMONITIS

Two forms of idiopathic interstitial pneumonitis have been identified in patients with HIV infection: lymphocytic interstitial pneumonitis (LIP) and nonspecific interstitial pneumonitis (NSIP).

### Lymphocytic Interstitial Pneumonitis (LIP)

It is histologically a well-defined complication. Lymphocytic interstitial pneumonitis frequently occurs in children younger than 13 years who have been infected with HIV perinatally, but occasionally is also seen in adults (1% cases). The pathogenesis is unclear, but it is thought to be an immunological reaction to HIV or EB virus within the lung.

Signs and symptoms are nonspecific and patients develop dyspnea. Symptoms may resolve spontaneously or progress to respiratory failure. Diagnosis is by histology and exclusion of other opportunistic infections. The characteristic X-ray finding is of bilateral reticulonodular infiltrates, predominantly in the

lower lobes but rarely in the entire lung. BAL fluid reveals no organisms, but only CD8+ lymphocytes.

Lung biopsy shows firm grey nodules characterized by lymphocytic infiltrate. Though granulomas are not seen lymphocytic infiltrate with germinal center formation may be seen. This condition is generally self limited and no specific treatment is necessary. In severe cases, antiretroviral therapy, intravenous immunoglobulin and corticosteroids have been tried.

## Nonspecific Interstitial Pneumonitis (NSIP)

This entity is well-described in adults with HIV, and is 10 times commoner than LIP. The radiographs show bilateral reticulonodular infiltrates in most patients, while histology shows an interstitial inflammatory infiltrate with a predominance of lymphocytes and plasma cells. In contrast to LIP, a follicular pattern with germinal center formation is not seen. The etiology of this condition is not known, but it may occur as a result of previous opportunistic infections or as an immune response to HIV in the lung. There are no specific clinical features; symptoms are mild and condition may resolve or stabilize spontaneously.

## Nonspecific Emphysematous Disease

The presence of radiological changes of cystic lesions (blebs, bullae, and pneumatoceles) in the lungs of patients with HIV is called as emphysema like disease or cystic lesions. The cause is unknown; the potential etiologies include IV drug abuse, recurrent infections, and direct effect of HIV infection.

Abnormalities in airway function: These are usually mild and reversible with bronchodilators. Bronchiolitis obliterans organizing pneumonia does not show a higher incidence in HIV-positive population and the presentation is same as in HIV-negative population.

## PRIMARY PULMONARY HYPERTENSION

Incidence of this entity in HIV positive population is 1:200. There is no correlation with stage of HIV or occurrence of opportunistic infections. As compared to immunocompetent patients with primary pulmonary hypertension, patients with HIV related disease are younger, less dyspneic and have lower peak pulmonary artery pressure.

Pulmonary hypertension in HIV infection occurs due to release of epidermal growth factors which leads to induction of nitrous oxide that causes increased vessel tone and endothelial proliferation. Secondly, it can also occur due to obstructive talc granulomas in small pulmonary arteries in IV drug users and pulmonary hypertension associated with chronic liver disease and portal hypertension.

Clinical presentation is nonspecific with atypical chest pain and dyspnea on exertion. The clinical signs of pulmonary hypertension may be evident (Fig. 75.16). Echocardiography and right heart

**Fig. 75.16:** Primary pulmonary hypertension.

catheterization with pulmonary arteriogram may be necessary to confirm the diagnosis. Antiretroviral therapy does not appear to be of clear benefit, but the disease may respond to epoprostenol. However, the prognosis is quite poor with a median survival range of 2 years.

## PULMONARY MANIFESTATIONS OF IRIS

Immune reconstitution inflammatory syndrome (IRIS) may occur within days or weeks after the initiation of HAART (early IRIS) or weeks after the initiation of HAART (late IRIS).<sup>2</sup>

### Mycobacterial Infections

Tuberculosis is among the most common diseases associated with IRIS. The onset of IRIS related to *Mycobacterium tuberculosis* is usually in the first 2–3 weeks after starting HAART and typically within the first 2 months of therapy.<sup>30,31</sup> Most cases represent paradoxical cases of IRIS as the majority of cases develop in patients who are improving on therapy for known TB, but are subsequently found to be HIV-infected and therefore begun on HAART.<sup>28</sup> Pulmonary involvement may be encountered in 84% cases.<sup>32</sup> Radiographic infiltrates may worsen in areas of prior disease in 50% of the cases or may reflect new areas of involvement.

Pulmonary complications with MAC have been described in 20% cases as a part of IRIS. Specific manifestations include new infiltrates on chest X-ray, inflammatory masses, cavitary lesions, and endobronchial lesions.<sup>30,32,33</sup>

### Fungal Infections

Cryptococcus associated IRIS with pulmonary involvement is seen in 20% cases. Chest X-ray findings include diffuse infiltrates and nodules. Pleural effusions are rare. Worsening

of *Pneumocystis jiroveci* pneumonia following the initiation of HAART has been described in several case series.<sup>34,35</sup> Manifestations of IRIS in patients consist of fever, worsening hypoxia, and alveolar opacities on chest X-ray. Bronchoalveolar lavage shows lymphocytosis with elevated CD4 and CD8 T cell counts.<sup>34</sup> Potential risk factors for the development of PCP-associated IRIS are severe pneumonia on presentation ( $\text{PaO}_2 < 70$  mmHg), marked decrease in HIV viral load on initiation of highly active antiretroviral therapy (HAART), close proximity of HAART to PCP treatment and cessation of steroids prior to initiation of HAART.<sup>34</sup>

Histoplasmosis-associated IRIS has been infrequently reported with atypical presentations of disseminated disease. Findings include pulmonary nodules and mediastinal adenopathy.

Only one case of pulmonary aspergillosis with worsening of lung infiltrates and inflammation suggestive of IRIS has been reported till date.<sup>35</sup>

### Viral Infections

Pulmonary complications of IRIS due to viral infections appear to be less common than those due to mycobacterial or fungal infection.

### Sarcoidosis

Most cases of sarcoidosis have occurred in context of a significant decrease in HIV viral load and increase in CD4 count lending support to the possibility that sarcoidosis may reflect a form of IRIS in these patients.<sup>36</sup> Pulmonary manifestations include restrictive and obstructive ventilatory defects with decrease in diffusing capacity on pulmonary function testing. Chest X-ray findings include parenchymal opacities which can include small micronodules, ill-defined lesions, cavitary nodules, or cysts. Nodules are usually distributed in subpleural regions and along bronchovascular bundles.

### Malignancy

Kaposi sarcoma may present as a manifestation of IRIS, and rarely non-Hodgkin lymphoma (NHL) may develop or worsen as a manifestation of IRIS.<sup>37</sup>

### Treatment of IRIS

Treatment includes continuation of primary therapy against the offending pathogen in order to decrease the antigenic load, continuation of effective HAART, and judicious use of anti-inflammatory agents.<sup>38</sup>

1. Milder IRIS: Continue HAART, antimicrobial agents, and nonsteroidal anti-inflammatory drugs.
2. Severe life-threatening IRIS: Needs oral prednisolone, approximately 1–2 mg/kg. The exact duration and dose of the steroid is variable and depends upon clinical severity. Sometimes the duration of the steroid therapy may extend to 6 months or even 1 year. Consider discontinuation of HAART

in case of severe life-threatening IRIS (e.g., encephalitis, ARDS, cerebritis, and perilesional cerebral edema).

The occurrence of IRIS does not require any modification in the treatment of OIs. Maintenance treatment for OIs should not be changed and previously completed OI treatment (e.g., for tuberculosis) should not be reinitiated. Also, the dosages of chronic suppressive treatment for an OI should not be increased.

### Summary

- Apart from increased incidence of upper respiratory tract infections such as otitis media and sinusitis, recurrent bacterial pneumonias are also common in HIV disease. Common causes are *S. pneumoniae*, *H. influenzae*, *Pseudomonas aeruginosa*, and *S. aureus*. Atypical pathogens like *Legionella pneumophila*, *Mycoplasma pneumoniae*, *Chlamydia* are other rare causes. Clinical, radiological presentation and treatment are similar to non-HIV individuals. Apart from bacterial pneumonias, mycobacterial infections are of great relevance in India.
- *M. tuberculosis* is the single most commonly seen co-infection in HIV-infected individuals in India. TB and HIV share a symbiotic association, and TB can occur at any stage of HIV disease. The clinical presentation in patients with lower CD4 counts includes disseminated lesions, resemblance to PCP, and associated extrapulmonary involvement. Microbiological analysis of respiratory secretions, radiography, and newer molecular techniques are essential for diagnosis. Treatment of drug-susceptible tuberculosis is generally as effective in HIV infected patient as it is in the general population, but modifications taking into consideration drug interactions should be done. MDR/XDR tuberculosis should be suspected in retreatment/defaulters/non-responders and close contacts of MDR TB. Treatment should include at least three drugs to which organism is sensitive and should be continued for at least 2 years or 12 months beyond sputum conversion, whichever is later.
- MAC are the group of organisms that are ubiquitous in the environment, and infection occurs when CD4 count is less than  $0.1 \times 10^9/L$ . Pulmonary involvement occurs as a part of multisystem disease. The infection is resistant to first-line antituberculous therapy, but like tuberculosis requires combination therapy with at least three active drugs, and therapy should continue lifelong unless appropriate ART is instituted.
- As HIV disease progresses with diminishment in CD4 counts, other pathogens present with pulmonary involvement. CD4 counts less than 200/microliter considerably increase the chances of PCP. Classical clinical presentation is with fever, night sweats, progressive dyspnea, and chest pain. Diagnosis is based on the demonstration of *Pneumocystis jirovecii* in respiratory secretions in conjunction with radiological and enzymatic analysis.
- Apart from these common conditions, fungal pneumonias caused by *Cryptococcus*, *Aspergillus* and *Histoplasma* spp. may be seen. Toxoplasmosis may also present with pulmonary involvement, while herpes virus infections may also involve the lung. The diagnosis of these rarer conditions requires a high index of suspicion and strong microbiologic support. Treatment of these conditions requires a multidisciplinary approach involving a pulmonologist.
- Non-infectious complications include malignant complications like non-Hodgkin lymphoma, Kaposi sarcoma, and idiopathic interstitial pneumonitis including lymphocytic and non-specific interstitial pneumonitis.
- Most common pulmonary manifestations of IRIS include mycobacterial infection. Cryptococcal lung disease may emerge in 20% cases. Rarely, sarcoidosis, Kaposi sarcoma, and other lymphomas may manifest. Treatment includes continuation of primary therapy against offending agents to decrease the antigenic load, as well as effective HAART and judicious use of anti-inflammatory agents.

# Neurological Manifestations of HIV

Arun B. Shah • Ramshekhar Menon

## 76

### Introduction

The availability of potent therapy for human immunodeficiency virus (HIV) infection (highly active antiretroviral therapy [HAART]) has dramatically changed the outlook for infected patients. Opportunistic infections including those that affect the central nervous system (CNS) are very common in developing and under developed countries which harbor the major disease burden of HIV infection, especially in those patients who are not receiving antiretroviral therapy. The 2006 estimates suggest national adult HIV prevalence in India is approximately 0.36%, amounting to between 2 and 3.1 million people. While neurological disease may be the presenting manifestation in 7–20% of cases, the prevalence of neurological complications is about 40–70%.<sup>1,2</sup> Besides its association with opportunistic infections (OI), HIV itself can infect the central and peripheral nervous system, even in patients on HAART (Table 76.1). In a large study from India, neurological complications were seen in 20.4% of outpatients as opposed to 44.5% of hospitalized HIV-positive patients.<sup>3</sup> The most common manifestation was peripheral neuropathy (28.3%), followed by meningitis (17.9%) and central nervous system (CNS) mass lesions (16%), of which toxoplasmosis was the most common. In another study, OI of CNS (cryptococcosis, tuberculosis, toxoplasmosis, pyogenic meningitis, and neurosyphilis) were reported to be 4 times more common than noninfectious lesions, like HIV-associated dementia.<sup>4</sup> Survival after the diagnosis of HIV infection is strongly correlated with the initial acquired immunodeficiency syndrome (AIDS) defining diagnosis.<sup>1</sup> Specifically patients suffering from neurological OI or primary CNS lymphoma (PCNSL) have shorter survival rates.<sup>5</sup> In addition low CD4+ counts, anemia, lower functional status, female sex, and older age are also associated with shortened survival.<sup>5</sup> Table 76.2 shows a comparison of the incidence rate in the pre-HAART era with the present day scenario. In other studies involving homosexuals and drug users with HIV infection a similar drop in incidence rate for HIV dementia and opportunistic infections, e.g., toxoplasmosis has been noted, when compared with the period prior to 1996 with

the subsequent years.<sup>6</sup> However, another recent study showed that the incidence of progressive multifocal leukoencephalopathy (PML) did not significantly differ between the pre-HAART and

**Table 76.2:** Mean Incidence Rate of HIV-1 Associated Neurologic Diseases during Three Time Periods in the Multicenter AIDS Cohort Study<sup>6</sup>

Disease	1990–92 (Monotherapy)	1993–95 (Dual therapy)	1996–98 (HAART)
HIV dementia	21.1	17.8	10.5
Cryptococcal meningitis	5.0	2.5	1.5
Toxoplasmosis	5.4	3.8	2.2
PML	2.0	1.8	1.5
CNS lymphoma	2.8	4.3	0.4

HAART period, although a prolonged survival of PML cases was noted.<sup>7</sup> One has to keep in mind the fact that a host of diseases can occur simultaneously in an immunocompromised host.

The first report of neurological involvement in an HIV-infected patient from the subcontinent was in August 1986—transmission associated AIDS dementia.<sup>8</sup> However in this patient, present criteria for HIV encephalopathy were not met as the fundus evaluation favored toxoplasmosis/tuberculosis. This however highlighted the beginning of AIDS epidemic as was smoldering

in the rest of the world. What is evident now is that the main burden of the disease, especially in the subcontinent, is due to OIs with relatively high mortality. In the era of HAART with better control of OIs and advances in diagnostic facilities the primary HIV-related illnesses are being detected, though less in comparison. Still the accessibility of HAART in a developing country like India remains frugal, necessitating greater state and social responsibility to ensure it reaches the needy.

## Neuropathology and Pathogenesis

The CNS is protected from infectious pathogens and circulating toxins by the blood–brain barrier (BBB), or the blood–nerve barrier in the peripheral nervous system. Lentiviruses such as HIV enter the nervous system through a process termed *neuroinvasion*.<sup>9</sup> HIV-1 infects leukocytes in the periphery by way of engagement of the CD4 molecule coupled with the chemokine coreceptor CXCR4 or CCR5. Antibodies to galactosyl ceramide inhibit entry of HIV into neural cell lines. The infected leukocytes subsequently cross the BBB, thereby transporting the virus into the nervous system much like a Trojan horse.<sup>10</sup> In the nervous system, HIV infects infiltrating macrophages, microglia, and astrocytes, indicative of *neurotropism*. It does not infect neurons, oligodendrocytes, or

Schwann cells. This process culminates in cell injury and death involving neurons, astrocytes, and neural stem cells.<sup>11,12</sup>

The pathologic hallmarks of advanced HIV infection of the CNS include HIV encephalitis, defined by multinucleated giant cells, viral antigen detection, perivascular cuffs, and diffuse white matter pallor.<sup>13</sup> Neurovirulence results in neuronal cell death and also synaptodendritic “pruning”.<sup>14</sup> Activation of monocyte lineage cells result in production of procytokines, eicosanoids, nitric oxide, and quinolinic acid which are neurotoxic. Although it is true that the consistent host response to HIV infection is neuroinflammation, each host mounts a distinct profile of immune gene activation in the nervous system based on the host’s unique genotype and phenotype. Specific brain derived HIV-1 sequence is associated with enhanced *in vivo* and *ex vivo* neurovirulence. Molecular sequence diversity is significantly greater in viruses derived from blood and brain in demented patients compared with nondemented AIDS patients, suggesting that the diversity contributes significantly to the neuro-toxicity.<sup>15,16</sup> Diversity is caused by the error prone reverse transcriptase, high rates of replication, in permissive cells, intense immune selection, and recombination between closely related and disparate viral strains.<sup>17</sup> Of interest, HIV can segregate into organ-specific strains within a single host that act in concert to escalate the disease course; e.g., immunosuppressive and neurovirulent viral strains cooperating within a single host.<sup>18</sup> Table 76.3 emphasizes the neuropathological heterogeneity of HIV infection leading to multiple sites of affliction by the virus directly or due to opportunistic infections arising out of the immunocompromised state.

Overall, considering the myriad of diagnostic possibilities in an HIV-infected patient, Figure 76.1 should be useful to the clinician to approach, investigate, and arrive at a diagnosis. Site specific diseases will be discussed further.

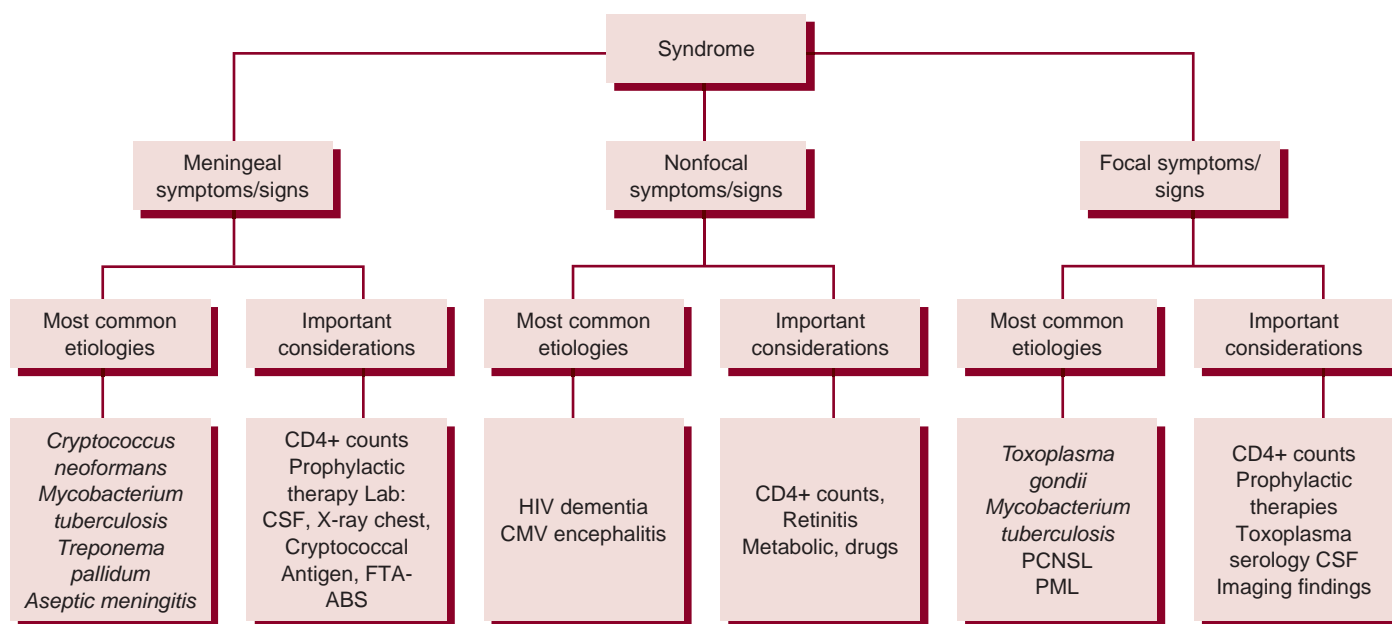

## Site Specific Diseases

### MENINGITIS

#### Aseptic Meningitis

It is usually a consequence of primary HIV infection as part of seroconversion illness. The onset varies from 2 to 4 weeks after exposure but can appear as early as 6 days or as late as 6 weeks. Common associated symptoms during the seroconversion phase include fever, generalized adenopathy, myalgias, arthralgias, truncal rash, and headache. It has also been shown that subclinical meningitis may be seen in a subset of patients who underwent lumbar puncture for other reasons.<sup>19</sup> Laboratory data also indicate that mild mononuclear pleocytosis may be seen in up to 18% of asymptomatic patients.<sup>20</sup> CSF analysis reveals elevated protein (less than 100 mg/dL) usually mild, mononuclear pleocytosis (>25/ $\mu$ L). Exclusionary studies (cryptococcal antigen, bacterial/viral cultures, polymerase chain reaction, and cytology) are necessary and the significance of CSF HIV-1 RNA estimation is unknown. In acute meningitis, symptoms of fever, headache, and meningeal signs resolve within 1 month. Patients of chronic meningitis are usually afebrile, suffer from headaches while some patients may suffer seizures, confusion, cognitive deficits cranial nerve palsies, and idiopathic intracranial hypertension<sup>21</sup> and its relation to HIV is usually a diagnosis of exclusion.

Similarly, encephalitis as a complication of seroconversion illness usually is a post febrile encephalopathy with seizures and some cases coma. It resolves in 2–3 weeks. Fatal necrotizing leukoencephalopathy and meningoencephalitis due to either cessation of HAART or loss of the host’s ability to control

**Fig. 76.1:** Approach to CNS infection in HIV + patient. Adapted from Ref no. 22.

**Fig. 76.2:** HSV-2 encephalitis: T1 weighted MRI of a seropositive patient presenting with seizures followed by global encephalopathy. CSF was consistent with a hemorrhagic meningitis. Hypointensities are seen over bilateral temporal cortices and limbic regions. CSF HSV-2 DNA PCR was positive. CD4+ counts of 380/mm<sup>3</sup>.

chronic CNS HIV have also been described.<sup>22</sup> Improvement after change of HAART regimen has been noted. Other encephalitic illnesses need to be ruled out in this setting as evident from Figure 76.2.

### Cryptococcal Meningitis

It is the most common manifestation of systemic fungal infection in HIV-infected persons, especially in the developing world; in some areas, it is the second most common OI after tuberculosis. The CD4+ cell counts are usually <100 cells/mm<sup>3</sup>. It is caused by the encapsulated yeast like fungus *Cryptococcus neoformans* var. *neoformans*, acquired from the soil and feces of birds via inhalation and subsequent dissemination from lungs to other organs. Cerebrospinal fluid (CSF) is particularly prone to infection because it is a good growth medium and lacks complement and immunoglobulin. Theories behind its pathogenesis include dissemination of newly acquired infection, reactivation of latent infection due to immunosuppression, and reactivation of latent infection due to immune reconstitution syndrome. Enhanced immune function secondary to HAART may unmask latent infection and precipitate clinically apparent meningitis.

A large series of 335 HIV-seropositive patients with cryptococcal meningitis revealed headache with intracranial hypertension to be the predominant clinical feature.<sup>23</sup> Others include fever, altered sensorium and seizures. Papilledema was the dominant clinical sign. One third of the patients had disseminated infection in the lungs, kidney, or skin. Cranial neuropathies and focal deficits were seen in a small subset of patients. Neuroimaging is to be carried out in all suspected cases of chronic meningitis. While majority of the scans may be normal, they may show diffuse

cortical atrophy, hydrocephalus, or focal masses in the form of punctuate nonenhancing foci of CSF density correlating with the presence of cryptococci in the Virchow-Robin spaces (Fig. 76.3). A lumbar puncture with manometry is the diagnostic procedure of choice. CSF analysis usually reveals lymphocytic pleocytosis with raised protein and low sugar level. India ink stain reveals encapsulated organisms. A positive fungal culture is considered to be the gold standard. This also helps to determine the fungal species and drug susceptibility in cases of recurrent infection. Antigen detection tests including latex agglutination and enzyme immunoassay are >90% sensitive and specific.

Therapeutic practice is to initiate induction therapy with amphotericin B 0.7–1 mg/kg/day plus 5-flucytosine 100 mg/kg/day for 2 weeks followed by fluconazole 400 mg/day for a minimum of 10 weeks. After this period fluconazole dose may be reduced to 200 mg/day depending on the therapeutic status of the patient. Flucytosine may not be routinely used due to lack of availability and high cost. Hence, monotherapy with amphotericin B is initiated and fluconazole added simultaneously or after 2 weeks. Monitoring of serum creatinine and potassium levels should be done frequently. Although liposomal preparations of amphotericin have many advantages such as the administration of higher doses over a short period of time with less adverse events, the cost is prohibitive. Fluconazole should be continued till the CD4+ counts exceed 350/mm<sup>3</sup> and cultures are negative. Itraconazole albeit may be less effective but may be suitable for those patients who do not tolerate fluconazole. If there is no clinical resolution after acute treatment (8–10 weeks), a repeat lumbar puncture should be done. If *Cryptococcus* is still grown from CSF, then acute treatment should be continued considering possible dose changes to the existing therapy or addition of other antifungal agents. Repeat susceptibility testing to antifungal

**Fig. 76.3:** Cryptococcomas: T2 weighted MRI showing prominent hyperintensities in the deep subcortical regions which are actually gelatinous appearing pseudocysts that extend along the enlarged perivascular spaces.

agents may be helpful in selecting the most effective drugs. Elevated intracranial pressure occurs in up to 75% of the patients with cryptococcal meningitis and is an important contributor to mortality and morbidity. Patients with raised intracranial tension should be treated aggressively. The principal intervention for reducing elevated intracranial pressure is percutaneous lumbar drainage. In patients with normal baseline opening pressure ( $<200$  mm H<sub>2</sub>O), a repeat lumbar puncture should be performed 2 weeks after the initiation of therapy to exclude elevated pressure and to evaluate culture status. In patients with elevated baseline opening pressure, lumbar drainage should be done to reduce pressure by 50%. Daily lumbar punctures are carried out to maintain CSF opening pressure in the normal range. Once CSF pressure is normal for several days, lumbar puncture can be stopped. When frequent lumbar punctures are required or fail to control symptoms of elevated intracranial pressure, a lumbar drain may be considered. Ventriculoperitoneal shunting may be considered when the above measures fail to control raised intracranial pressure and also in patients with hydrocephalus.<sup>23</sup>

Antiretroviral therapy is usually started when the clinical condition of the patient is relatively stable especially in those with very low CD4+ ( $<100$  cells/mm<sup>3</sup>) counts. The possibility of immune reactivation inflammatory syndrome (IRIS) should be considered when patients develop new neurological deficits with an improving CD4+ count.<sup>24</sup> Patients with cryptococcal IRIS can present as meningitis, intracranial mass lesions, pulmonary cavitation, or lymphadenitis.<sup>25</sup> It usually occurs after a few weeks or a few months and is treated with steroids or nonsteroidal anti-inflammatory drugs (NSAIDs).

The poor prognostic factors are depressed levels of consciousness, signs of raised intracranial pressure, depressed CSF cell counts and glucose levels and CSF cryptococcal antigen titer  $> 1024$ .<sup>26</sup> A significant proportion of patients can develop various neurological sequelae, which include visual loss, decreased mental capacity, hearing loss, permanent cranial nerve palsies, and hydrocephalus.<sup>23</sup>

## Syphilitic Meningitis

In patients with HIV infection, neurosyphilis appears to develop within a shorter interval than is usual for development of the disease. In addition, the prevalence of acute syphilitic meningitis, ocular symptoms or signs (particularly uveitis), and hearing loss is increased. Asymptomatic patients with positive serologic findings should undergo CSF examination for exclusion of neurosyphilis. The recommended treatment for neurosyphilis consists of a 10- to 14-day course of either aqueous crystalline penicillin G, 3 to 4 million units IV every 4 hours or procaine penicillin, 2.4 million units IM daily, with oral probenecid, 500 mg 4 times a day. In patients who are allergic to penicillin, desensitization should be considered. Alternatively, ceftriaxone, 2 g IV or IM daily, or amoxicillin, 3 g plus probenecid, 500 g twice a day can be given for 15 days. CSF examination should be repeated at 3–6 monthly intervals for the first year and then every 6 months,

up to 2 years. Ideally, the CSF cell count should normalize and the protein levels also become lower, but the coexistent HIV infection may preclude this. However, a declining VDRL titer in CSF confirms adequacy of treatment.

## Tuberculous Meningitis

HIV infection increases the risk of tuberculosis, and it was anticipated in the year 2000 that 14% of the 10.2 million newly detected cases of tuberculosis would be in patients with HIV infection.<sup>27</sup> Extrapulmonary disease is more common in patients with advanced immune compromised. TBM is the most serious manifestation of tuberculosis and is one of the three most common neurological OIs seen in India.

A large pathology series in Western India revealed a reduced inflammatory response in the meninges, with a paucity of basal exudates which is in tandem with the minimal meningeal enhancement seen on CT scans.<sup>28</sup> Microscopic infarcts secondary to arteritis were seen in the basal ganglia and parenchyma. AFB was present in large quantities within the lesions. This paucity of immune response was also reflected in the CSF.

Presenting symptoms include fever, headache, vomiting, weight loss, seizures, and impaired vision. Meningeal irritation, hemiplegia, and paraplegia are infrequent compared to seronegative patients. Cranial neuropathies are significantly more common, especially in advanced stages of infection. It is thus a more rapid and fulminant disorder. Clinical difference is probably evident between Indian patients and those from the West as the former are significantly more immunocompromised.<sup>28</sup>

CSF may not be as reactive as in immunocompetent patients, thus rendering the diagnosis of TBM presumptive. However, serial large volume cultures may increase the yield of detection, and identification by polymerase chain reaction (PCR) is specific but not sensitive (Table 76.4). CSF adenosine deaminase (ADA) activity measurement of more than 5 IU/L has a sensitivity of 60–80% and specificity of 70–90%. Tests like CSF tuberculostearic acid, blood gamma-interferon levels, and BACTEC culture are reported to improve detection corroboratively. Neuroimaging may show communicating or noncommunicating hydrocephalus. It may also demonstrate infarcts, tuberculomas (Fig. 76.4), and tuberculous abscesses. Identification of active tuberculosis at

**Table 76.4:** CSF Diagnostic Tests Available for TBM<sup>7</sup>

	Sensitivity
Acid-fast staining of bacteria	5–25%
Tuberculostearic acid	50–75%
Mycobacterium isolation from routine single lumbar puncture	20–40%
Mycobacterium isolation from 3 high-volume lumbar punctures	50–80%
Polymerase chain reaction assay detection of nucleic acid	50–75%
Detection of antibody to <i>M. tuberculosis</i>	55%

**Fig. 76.4:** Intracranial tuberculoma: An intensely ring-enhancing lesion over the left frontal region which was hypointense on T1 and T2 images. This seropositive patient had systemic evidence of tuberculosis.

another anatomical site aids the diagnosis though parallel tracking (infection by multiple pathogens) is notorious in HIV-infected hosts.

Three or more drugs are required for a minimum period of 12 months in established cases. Duration of therapy may need to be prolonged (up to 18–24 months) especially in those with coexistent tuberculomas. First line drugs include isoniazid (5–10 mg/kg/day; not >300 mg/day) and rifampicin (10 mg/kg/day; not >600 mg/day); Rifabutin is preferred if protease inhibitors are part of the HAART regimen. Two additional drugs need to be given during the first 3 months. Pyrazinamide (15–30 mg/kg/day) is given along with either streptomycin (15 mg/kg/day) or ethambutol (15–25 mg/kg/day). Atypical mycobacteria may require usage of second line drugs, e.g., ciprofloxacin (1500 mg/day), ethionamide (500–1000 mg/day), rifabutin, kanamycin, or cycloserine. Multidrug resistance, defined as resistance to at least isoniazid and rifampicin, is most common in patients infected with HIV, and the death rate is much higher when these organisms cause meningitis.<sup>29</sup> Steroids are added in cases presenting with altered mentation, focal signs, and coexistent tuberculomas especially those >2 cm in size. A recent study showed that while steroids significantly reduced the risk of death, they did not reduce the disability 9 months after treatment initiation.<sup>30</sup> Of note, survival benefit was not observed in the HIV-infected patients enrolled in the study. Deaths among the HIV-infected subjects occurred at a constant rate throughout follow-up. This observation, combined with the fact that none of the HIV-infected subjects in the study received HAART, suggests that HIV infection was a major contributor to death.

Even before the advent of HAART, “paradoxical responses” were noted in patients undergoing treatment for TBM. Such individuals developed CSF polymorphonuclear pleocytosis or brain tuberculomas early in course of treatment, presumably due

to improved ability to respond immunologically or to greater antigenic stimulation as a result of bacterial death. IRIS in patients undergoing treatment for pulmonary or lymphatic tuberculosis is well-documented. Active infection must always be excluded. Preferably, treatment for tuberculosis should take priority over that for HIV infection in HIV-infected tuberculosis, and HAART may be administered after the treatment of tuberculosis, but simultaneous layering with other infections may render the decision difficult.

Though it is believed that HIV-infected patients with TBM have a higher mortality rate, there are no studies that have examined the course of the disease in HIV-infected patients treated with HAART.

## Other Causes of Meningitis

Meningitis secondary to *Listeria monocytogenes*, *Salmonella* sp., and organisms causing pyogenic meningitis are being seen with increasing frequency in seropositive patients. Acute meningitis therapy should thus include ampicillin in addition to the standard medications. Other causes include nocardiosis, histoplasmosis, coccidioidomycosis, mucormycosis, and disseminated candidiasis. Lymphomatous meningitis is a complication of AIDS related systemic lymphoma. The incidence of systemic non-Hodgkin lymphoma is over 100 times increased and Hodgkin disease is approximately 10 times increased in the HIV-infected population.<sup>31</sup> Factors predicting a CNS involvement include Epstein–Barr virus (EBV) infection, extra nodal disease at diagnosis, and a non-CNS relapse.<sup>32</sup> An examination of the CSF for malignant cells is mandatory in all AIDS patients with systemic lymphoma. Steroids can be effective for symptomatic treatment of headache and pain. The appropriate treatment should include intraventricular administration with an Ommaya reservoir of either methotrexate 12 mg or cytosine arabinoside 50 mg or thiotepea 10 mg biweekly until the CSF is devoid of malignant cells.

## DIFFUSE ENCEPHALOPATHIES

### HIV-Associated Dementia (HAD)

Prior to availability of therapy, up to 60% of patients with AIDS developed obvious or subclinical cognitive decline. In the era of HAART incidence of HIV dementia is reported to be only 1%<sup>33</sup> though two case series have placed the figure between 4–13%.<sup>34,35</sup> Differences in neurovirulence of HIV subtypes are believed to be responsible for variations in incidence rates between developed and developing nations.

The development of HAD is among the most devastating consequences of HIV-1 infection because of its unique and progressive clinical manifestations. Clinical and pathological severity does not correlate particularly well. Neurotoxins include the viral envelope glycoprotein gp120 and cytokines induced by systemic and cerebral HIV infection. N-methyl-D-aspartate (NMDA) receptor activation and calcium influx resulting from toxins elaborated by interactions of HIV-infected monocytes and macrophages and cytokines have been proposed as the mechanisms

**Box 76.1****Features of HIV-1 Associated Neurocognitive Disorders (HAD, Mild Neurocognitive Disorder)**

- Neurocognitive dysfunction: memory impairment, poor concentration, psychomotor slowing.
- Emotional disturbance: apathy and social withdrawal, irritability, mental inflexibility, and loss of libido.
- Motor abnormalities: weakness, ataxia, clumsy gait, tremor, bradykinesia, increase in tone, hyper-reflexia, spasticity, abnormal eye movements.

of neuronal injury. Histologically, the major changes are seen in the subcortical areas of the brain, and this possibly explains the clinical picture of “subcortical dementia”. Remarkable diversity is exhibited in its clinical presentations as shown in the table below, including movement disorders, mania, and psychosis (Box 76.1).

The diagnosis of this condition may be more difficult to make because of comorbidities such as prior substance abuse, head injury, or coinfections such as hepatitis C infection. The full spectrum of asymptomatic neurocognitive impairment remains undefined in terms of impact and outcomes; however, the diagnosis of HAD heralds a prognosis for diminished survival, regardless of whether the patient is receiving HAART.<sup>32,36,37</sup>

Symptoms typically begin once an individual's CD4<sup>+</sup> count drops <200 cells/mm<sup>3</sup>. Clinical risk factors also include high CSF or plasma viral load, anemia, extremes of age, intravenous drug abuse, and several host genetic polymorphisms.<sup>33</sup> Radiologic features accompanying HAD include cerebral and basal ganglia atrophy and diffuse periventricular white matter hyperintensities on MRI T2-weighted images (Fig. 76.5). MR spectroscopy shows diminished N-acetyl aspartate, a neuronal metabolite, together with increased choline levels indicative of inflammation. CSF analyses to rule out OIs is mandatory; high protein and immunoglobulin G levels with pleocytosis are found in CSF of 66% of HAD patients.<sup>38</sup> Viral load in CSF appears to be predictive of HAD and is higher in demented than in nondemented HIV patients and in patients of HIV encephalitis.<sup>38</sup>

Tools for assessment and follow-up of the patients involve neuropsychological evaluation. Since HAD is a primarily subcortical dementia, it is not readily detected by the Folstein Mini-Mental Status Examination unless the patient is severely demented. Better tools include the International HIV Dementia Scale, the Mental Alteration Test, the Executive Interview, and the HIV Dementia Assessment.<sup>39–42</sup>

**Fig. 76.5:** HIV-associated dementia: Symmetrical periventricular white matter hyperintensities on T2 weighted MRI in a seropositive patient clinically diagnosed as HIV encephalopathy.

Metabolic encephalopathies including hypothyroidism and vitamin B<sub>12</sub> deficiency, medication side effects, substance abuse, and depression need to be considered while evaluating these patients. Pointers to the differential diagnosis with other opportunistic infection related encephalopathies are as in Table 76.5.

HAART regimens used in therapy consist of two nucleoside analog reverse transcriptase inhibitors (NRTIs) plus a protease inhibitor (PI) or a non-nucleoside reverse transcriptase inhibitor (NNRTI). Specific antiretroviral drugs have higher CSF penetration than others, including the NRTIs zidovudine (AZT), stavudine (d4T) and abacavir, the NNRTIs nevirapine, efavirenz, and the PI indinavir.<sup>43,44</sup> Combining ritonavir, a P-glycoprotein inhibitor, with indinavir may increase the latter level in the brain. In HAD, a combination of AZT/d4T (with or without lamivudine or abacavir) plus nevirapine would be an effective combination.<sup>44,45</sup> Dosage strategies are as below:

- Zidovudine 300 mg tid + any of the following:
  - Nevirapine 200 mg bid
  - Indinavir 800 mg tid
  - Efavirenz 600 mg qd
  - Nelfinavir 750 mg tid or 1250 mg bid

**Table 76.5:** HIV-Associated Dementia—Differential Diagnosis<sup>58</sup>

	HAD	CMV encephalitis	PML
<b>Features</b>	Memory disturbance, mental slowing, Gait abnormalities	Delirium, seizures, brainstem signs	Focal neurological signs
<b>Course</b>	Several months	Days to weeks	Weeks to months
<b>MRI</b>	Diffuse atrophy, symmetrical deep white matter diffuse hyperintensities	Normal or periventriculitis	Scattered asymmetrical subcortical white matter lesions
<b>CSF</b>	Nondiagnostic, immune activation less marked	PCR positive for CMV in 90%	PCR positive for JC virus in 60%

HAD, HIV-associated dementia; CMV, cytomegalovirus; PML, progressive multifocal leukoencephalopathy; PCR, polymerase chain reaction; MRI, magnetic resonance imaging; CSF, cerebrospinal fluid.

- Alternative NRTI agents:
  - Stavudine 40 mg bid
  - Abacavir 600 mg bid
- Zidovudine-naïve: start with 300 mg tid

Indinavir dose must be increased to 1000 mg when used in combination with nevirapine, which is cytochrome P450 inducer and decreases indinavir levels by 30%.

HAART shows some benefit in reversing HAD, although poor drug penetration, drug-resistant strains and emergence of a “burnt-out” phase of the disease appear to limit its efficacy. Neuropsychological performance is however improved in AIDS patients treated with HAART.<sup>40,41</sup> Memantine and human growth hormone are some of the many agents studied in clinical trials.<sup>38</sup>

Despite the reduction in the risk of prenatal HIV transmission due to early introduction of ART in pregnancy among children who are congenitally infected with HIV, a progressive encephalopathy can develop. The prevalence of neurologic involvement in HIV-infected children can be as high as 50% depending on the level of immunosuppression and treatment, usually in the first 2 years of life. Neurologic features of congenital HIV infection include microcephaly, delayed developmental milestones, spastic paraparesis, and rarely seizures.

HAART increases survival in patients with HAD. However, a recent longitudinal study showed that HIV-infected patients treated with HAART who were cognitively impaired were significantly more likely to die than those who were not cognitively impaired and that decreased survival among those with cognitive impairment was associated with lack of suppression of plasma viremia.<sup>46</sup>

## CMV Encephalitis and Ventriculoencephalitis

Most adults have serological evidence of latent CMV infection. The incidence of CMV disease has decreased substantially in the HAART era, and is now an uncommon cause of global encephalopathy in advanced AIDS (CD4+ count <50/mm<sup>3</sup>). Prior or active disseminated disease, such as retinitis, esophagitis, or colitis, may provide important clues to the neurological diagnosis. It typically presents as a subacute evolving confusional state and can resemble HAD. Focal cerebral signs, hyponatremia, and MRI showing periventricular enhancement are factors that favor a diagnosis of CMV encephalitis. CSF abnormalities are nonspecific. Pathological findings include microglial nodules and cytomegalic cells in cortical and subcortical gray matter, thought to be consistent with hematogenous spread of CMV to brain. CMV ventriculoencephalitis manifests with brainstem signs and often occurs on the background of retinitis or polyradiculomyelopathy. Dilated ventricles are seen on MRI. CSF in such cases may reveal elevated protein, polymorphonuclear or lymphocytic pleocytosis, and normal or low glucose levels. Ependymal necrosis and subependymal gliosis are seen on histopathology. As CMV viremia is quite common in late stage AIDS, and hence detection in this setting by culture, antigen testing, or PCR from blood does not help establish the diagnosis.

Systemic CMV infection may be treated using ganciclovir,

foscarnet, and cidofovir. All these drugs have major limitations in AIDS patients in view of the side effects and their virostatic properties. Induction therapy may be initiated with ganciclovir 5 mg/kg/day IV q8h for 2 weeks followed by maintenance with 5 mg/kg/day IV for 5 days/wk. Bone marrow toxicity is to be monitored. Foscarnet may be initiated at 60 mg/kg IV q8h for 2 weeks and maintained at 90 mg/kg/day. Renal toxicity limits its dosage. Cidofovir may be commenced at 5 mg/kg/week IV for 2 weeks followed by 2 weekly maintenance doses. Neutropenia, renal failure, and ocular complications need to be monitored. Effective HAART and thereby successful restoration of the immune response against CMV is the most efficacious therapy to improve the dismal outcome in these patients.

## FOCAL BRAIN DYSFUNCTION

### Cerebral Toxoplasmosis

*Toxoplasma gondii* is an intracellular parasite that can exist as tachyzoites, which are replicating organisms that cause an active disease; bradyzoites, which are nonreplicating and responsible for latent disease; and oocysts. Humans become infected by ingesting oocysts shed from cat feces or by ingesting bradyzoites in undercooked meat. Primary infection is asymptomatic in 90% of people. In the remainder, it causes a mononucleosis like illness or regional lymphadenopathy. After acute infection, organisms encyst in many tissues and persist for life. In most individuals, the only evidence of previous infection is a reactive serologic infection. In a study of 279 sera (165 healthy blood donors and 89 consecutive HIV-infected patients) from India, seroprevalence was 30.9% in immunocompetent adults and 67.8% in HIV infected. Recrudescence of toxoplasmosis occurs when CD4+ counts drop below 100 cells/mm<sup>3</sup>. In 80% of patients from the series in whom it was checked, it was above 200 cells/mm<sup>3</sup>.<sup>47</sup> Indian studies have noted that 9–28.6% of HIV patients with neurological manifestations had features consistent with toxoplasmosis.<sup>3,48</sup> Even before HAART, prophylaxis for *Pneumocystis pneumonia* with co-trimoxazole, which also provides prophylaxis against toxoplasma encephalitis, decreased its incidence. A recent study revealed that the risk of toxoplasmosis was higher in individuals who were antiretroviral naïve, who had lower CD4+ counts, and who had not received toxoplasma prophylaxis.<sup>49,50</sup>

Patients present with headache, fever, and confusion. Physical examination commonly shows fever, hemiparesis, ataxia, altered sensorium, seizures, and psychomotor retardation. Rarely, these patients have an encephalitic picture with fever and change in mental status.

As noted earlier, a significant proportion of patients have serum IgG antibody to *T. gondii*. In general, testing for IgM antitoxoplasma immunoglobulin has little value, although it may be more likely to be positive in individuals with the encephalitic form of the disease.<sup>22</sup> Neuroimaging typically shows round lesions that are isodense or hyperdense on CT or T1-weighted MRI. These may be located at the hemispheric gray-white matter, in the deep white matter, or in the basal ganglia. More than 90% of

**Fig. 76.6:** Contrast enhanced CT brain showing multiple disc-nodular enhancing lesions over the subcortical white matter with significant perilesional edema. Serum IgG Toxoplasma antibody levels were significantly elevated.

lesions enhance with contrast in a ring, nodular, or homogenous pattern (Fig. 76.6). MRI is more sensitive than CT in identifying multiple lesions. A single lesion on neuroimaging increases the likelihood of primary CNS lymphoma, while multiple lesions increase the likelihood of toxoplasma encephalitis. Functional studies have revealed increased thallium-201 uptake are seen with lymphoma, while no brain uptake is seen in patients with toxoplasma encephalitis.<sup>22</sup> PCR detection in CSF is specific but not sensitive. Greater specificity exists in estimation of antitoxoplasm IgG in CSF by immunofluorescence.<sup>47</sup>

As toxoplasmosis is probably the most common cause of a focal brain lesion with enhancement and edema, a treatment trial is often undertaken to confirm the diagnosis. Preferable candidates for a treatment trial include those with more than one enhancing CNS lesion on neuroimaging, detectable serum antitoxoplasma IgG, not on co-trimoxazole prophylaxis and in lieu of no other more likely diagnosis. A diagnosis is established if clinical improvement is seen within 1–2 weeks and radiographic improvement is seen within 2–3 weeks after initiation of the treatment (Fig. 76.7 a,b). Unless unavoidable,

**Fig. 76.7a,b:** Cerebral toxoplasmosis (before and after treatment): A post contrast image showing two disk enhancing lesions over the right basal ganglia and parasagittal regions which regressed in size after treatment.

steroids should not be part of a treatment trial because of nonspecific radiographic improvement which may be falsely attributed to empirical therapy.

Alternative diagnosis needs to be considered in absence of improvement. If a diagnosis cannot be reached brain biopsy should be considered.

Primary therapy is commenced with pyrimethamine 100–200 mg oral loading, then 75–100 mg daily along with sulfadiazine 1.5–2 g every 6 hourly. In case of sulfa allergy clindamycin 600–900 mg orally/IV is the appropriate therapy. Folinic acid 10–50 mg orally daily should be administered in both situations. A minimum duration of 6 weeks of primary therapy may be extended until there is no evidence of active disease on neuroimaging because persistent contrast enhancement is associated with a high recurrence rate. Chronic suppressive therapy or secondary prophylaxis may be continued with pyrimethamine 25–50 mg orally daily along with sulfadiazine 1 g tid to qid. Patients on clindamycin may be continued on 300–450 mg orally tid to qid. Effective antiretroviral therapy is an important part of maintenance therapy. A recent study revealed that patients of toxoplasmosis who began HAART within 2 months of diagnosis were less likely to have progression of their HIV disease compared with patients who began HAART more than 2 months after diagnosis.<sup>49</sup> Secondary prophylaxis can be discontinued in patients with a sustained increase in peripheral blood CD4+ counts to  $>200/\text{mm}^3$  for at least 6 months.

### Progressive Multifocal Leukoencephalopathy (PML)

PML is caused by the ubiquitous polyoma virus called JC virus. After infection, JC virus remains latent in blood, kidney, and perhaps in brain. The virus reactivates in the setting of immunosuppression, infects oligodendrocytes, and thus causes demyelination. It can also affect the gray matter. At least one third of the cases show perivascular round cell infiltrates as an indication of immunologic reaction. This type of reaction is considered hallmark of “slow virus” infection- typically characterized by the lack of a virus specific immune response.<sup>51</sup> The introduction of HAART led to a change in the pathology of PML, leading to a severe immune response in patients with AIDS and PML.<sup>52</sup> PML is thought to infect up to 4% of the patients with AIDS. A recent hospital based clinicoradiological study on HIV-positive patients with neurological manifestations detected that up to 14% of patients had features consistent with possible PML.<sup>53</sup>

Two case series revealed that in about 25–43% of cases, PML is the initial AIDS-defining illness.<sup>53,54</sup> Presenting symptoms and signs include limb weakness, limb incoordination, disorders of speech, and language or visual deficits. In a significant number cognitive deficits and/or a global encephalopathy may be evident. Seizures may be seen in up to 10% of patients.<sup>53</sup>

The best noninvasive method of diagnosing PML in an immunosuppressed patient is MRI. Predominantly, areas affected include the periventricular, frontal, and parieto-occipital white

**Fig. 76.8:** PML: A heterogeneous hyperintensity on T2-weighted MRI involving the left parieto-occipital white matter with involvement of the U fibers, splenium of corpus callosum and extending to the right side.

matter (Fig. 76.8), followed by cerebellum, brainstem, corpus callosum, basal ganglia, and rarely the spinal cord. The borders of the lesions are ill-defined and irregularly shaped and grow asymmetrically. Cortical involvement may be seen in up to 10% of cases and in 20% lesions are restricted to the posterior fossa. Subtle enhancement or space-occupying lesion like presentation may be seen in 10% of patients not undergoing immune reconstitution. MRS may reveal a reduced NAA and creatine content with increase in choline and lactate. Magnetization transfer ratios are characteristically lower in PML as opposed to cases of HIV encephalopathy. CSF analysis occasionally reveals pleocytosis and estimation of JC virus DNA PCR is sensitive as well as specific to the diagnosis.

Therapeutic response to cidofovir is partial. A large retrospective study analysis of 35 cases with PML showed a significantly shorter median survival in patients with HAART and cidofovir as compared to HAART only.<sup>55</sup> By far the best therapy of PML in AIDS patients is an optimal antiretroviral

**Fig. 76.9 a, b:** PML with lesions restricted to the posterior fossa before and after HAART: T2 weighted MR image on the left (July 2005) shows well-defined nodular hyperintensities over the medulla and left cerebellar white matter ( $CD4+ = 76/mm^3$ ). Resolution of lesions seen in repeat MRI (Oct 2007) with residual gliosis over the cerebellum ( $CD4+ = 357/mm^3$ ).

**Fig. 76.10:** Probable JC virus granule cell neuronopathy. T1 weighted MRI showing prominence of cerebellar foliae with absence of white matter involvement consistent with cerebellar atrophy. This seropositive patient presented with a progressive pancerebellar syndrome and  $CD4+$  counts of  $72/mm^3$ . Evaluation for alternative causes including for other hereditary degenerative ataxias was negative.

therapy (Fig. 76.9 a,b), significantly lowering HIV-1 RNA viral load in plasma and possibly in CSF and also improving cellular immune function. Many reports of IRIS in patients treated for PML with HAART have surfaced. The syndrome typically begins a few weeks of HAART and is characterized by clinical worsening and progression of previously MRI-defined lesions or development of new lesions, often with enhancement. Both fatal and benign courses are described.<sup>56,57</sup> Some experts suggest anti-inflammatory treatment in such cases with corticosteroids, but this approach is controversial. Looking at one aspect, restoration of immune function is required to clear JC virus and on the other hand fulminant inflammation with progressive neurological deterioration is not preferable.

Poor survival is associated with HIV-1 RNA plasma levels  $>500$  copies/mL and low  $CD4+$  counts  $<100/mm^3$ , JC viral load  $>100$  copies/ $mm^3$ .<sup>58</sup> HLA-A2 positive status is also thought to improve the survival of PML patients.<sup>58</sup>

### Cerebellar Degeneration in HIV-Positive Patient

Development of a subacute to chronic progressive pancerebellar syndrome in a seropositive patient renders a wide differential diagnosis. Possibilities include the following:

- Indirect effects of HIV infection
- Effect of cytokines on cerebellum
- JC virus (JCV) granule cell neuronopathy (Fig. 76.10)
- Toxins
- Alcohol
- Phenytoin
- Mercurial compounds
- Genetic (hereditary cerebellar atrophy)

A novel entity recently described is the JC virus granule cell neuronopathy, which leads to cerebellar atrophy.<sup>59,60</sup> The full-length sequence of a granule cell neuron-tropic JCV variant

(GCN) associated with lytic infection of granule cell neurons and cerebellar atrophy in an HIV-infected patient with PML was determined and compared with the sequence of the JCV isolate from the classic PML lesions present in the hemispheric white matter (HWM) of the same individual. A unique deletion was found in the C terminus of the VP1 gene of JCVGCN1, which encodes the major capsid protein, resulting in a frame shift and a total change of the C-terminal amino acid sequence of this protein. This deletion was not present in JCVHWM, suggesting that this mutation may be instrumental in facilitating entry or replication of JCV into granule cell neurons.

## Primary CNS Lymphoma

This B-cell origin neoplasm is considered to be an opportunistic infection caused by Epstein–Barr virus (EBV). Its incidence appears to be cumulatively rising because of the increased longevity of HIV-infected patients, following the efficacy of both prophylactic and therapeutic measures against OI and early initiation of HAART. The incidence as noted in two Indian series is very low (0.2–1.7%)<sup>3,48</sup> as opposed to 6–18% in Western literature.<sup>61</sup>

Patients present with focal or polyfocal symptoms and signs as in toxoplasmosis and PML. The temporal clinical profile is actually slower than in toxoplasmosis and faster than in PML, with patients presenting several days or a few weeks after the onset of symptoms, which may include headache, hemiparesis, aphasia, ataxia, behavioral changes, and altered mentation.<sup>62</sup> Distinctly, lymphomatous meningitis and ocular dissemination may be evident.

Neuroimaging is sensitive for detection of lesions, which are usually deep, well-circumscribed, subcortical, or subependymal with occasional mass effect and usually little contrast enhancement (Fig. 76.11) or surrounding edema.<sup>62</sup> CSF cytology requires concurrent

flow cytometry for detection of monoclonal B lymphocytes. This may be corroborated by CSF PCR for EBV DNA and brain biopsy. Thallium-201 SPECT may be useful in supporting the diagnosis of PCNSL and prompting early biopsy.

Prior to the era of HAART, a median survival of 2–3 months was seen. The most important factors related to survival include Karnofsky performance status, the CD4+ counts, elevation of CSF protein, and the absence of OI.<sup>63</sup> Prognosis is improved by a good HAART regimen and immune reconstitution, and vigorous attempts to suppress HIV replication are recommended in all patients.<sup>64</sup> Corticosteroids may be administered in case of mass effect. Though use of chemotherapy as recommended in seronegative hosts is limited to clinical trials, palliative whole brain irradiation therapy is recommended.<sup>62</sup>

## Stroke

Focal neurological signs and symptoms may occur due to cerebrovascular disease. Ischemic and hemorrhagic strokes have been reported in up to 4% of clinical series and up to 34% of autopsy series.<sup>65</sup> Association with HIV neuropathology itself is uncertain. HIV-associated thrombocytopenia, hepatic dysfunction and related coagulopathies, disseminated intravascular coagulation, PCNSL, Kaposi sarcoma, and occasionally toxoplasmosis are postulated mechanisms of intracranial hemorrhage. Ischemic stroke mechanisms include meningovascular syphilis, varicella zoster vasculopathy, and subacute bacterial endocarditis, vasculitis including TB vasculitis and procoagulant states. Long term effects of atherosclerosis, lipodystrophy, and metabolic syndrome induced by protease inhibitors are under evaluation. Angioinvasive fungi like aspergillus and mucor may cause strokes. Venous thrombosis may be encountered following dehydration induced by diarrheal illnesses or from thrombophilic states such as lupus anticoagulant.

## Seizures

New onset of seizures occur in 8% of adults and up to 20% of children who have HIV infection, although among patients followed regularly in HIV clinics, the prevalence of seizures is lower.<sup>38</sup> Generalized tonic-clonic seizures that can progress to status epilepticus is the commonest.<sup>66</sup> Toxoplasmosis, tuberculomas, cryptococcal meningitis, and PCNSL are the common causes of focal seizures. Other than OIs, medications, substance use or withdrawal as in alcohol or cocaine use, metabolic states and HIV infection per se may represent common causes of seizures. Drugs such as selective serotonin reuptake inhibitors, tricyclic antidepressants, ganciclovir, and foscarnet can lower the seizure threshold. In up to 50% of HIV-seropositive individuals, no underlying cause of the seizure is found except HIV itself.<sup>67</sup> A significant subset of these patients have a propensity to develop HAD. Because HIV-seropositive patients inherently have an increased rate of adverse drug reactions, up to a quarter of these patients will develop a rash with phenytoin. There is also a

**Fig. 76.11:** Primary CNS lymphoma: Contrast enhanced CT showing a homogeneously enhancing lesion over the left frontal subcortical white matter with juxtaventricular extent.

potential for drug interactions to occur between anticonvulsants and HAART because these groups of drugs are largely metabolized by the cytochrome p450 system. In addition, protease inhibitors competitively bind to albumin, thus altering anticonvulsant drug efficacy. Carbamazepine is however well-tolerated when it is coupled with regular monitoring of anticonvulsant drug levels and viral load.<sup>38</sup> Valproate has been shown to induce viral replication *in vitro*, although this has not been demonstrated *in vivo*.<sup>68</sup> Newer antiepileptic drugs like gabapentin, pregabalin, topiramate, and levetiracetam may be safer. The risks of using “first-line” anticonvulsants (carbamazepine, phenytoin, valproate) appear to be minimal, assuming viral load and anticonvulsant levels are measured regularly as part of ongoing care.

## Headache

Approach to a seropositive patient complaining of headache presents a diagnostic challenge. In view of advanced stages of immunosuppression as commonly encountered, secondary headache merits consideration. Primary headaches such as migraine with/without aura, tension type headaches, despite their higher prevalence in general population, are diagnoses of exclusion. An emergent neuroimaging study may often delineate granulomas, lymphomas, and meningitis. Papilledema may be seen in a large subset, requiring antiedema measures before attempting CSF evaluation in the absence of evident midline shift. Immunosuppressed hosts may not harbor significant pleocytosis, so attempts at isolation of organisms should be contemplated. Granulomatous lesions in the brain may follow chronic infections, e.g., tuberculosis, syphilis, and cryptococcosis. In such a setting, the review of past medical investigations and treatment will be more useful, especially when CSF and radiology are inconclusive and stereotactic biopsy is not feasible.

Management of primary headache disorders is no different from that in the general population. Depression merits consideration in chronic primary headaches, especially in the initial months of detection of seropositive status but as emphasized earlier, it remains a diagnosis of exclusion.

## Other Focal CNS Disorders

Cerebral abscesses may form after dissemination from infected indwelling catheters and in intravenous drug abusers. Other than bacteremia, tuberculous abscess, syphilitic gumma, bartonellosis and nocardiosis merit consideration. Fungal causes are also to be considered in view of angioinvasiveness. Neurocysticercosis may also be encountered. In patients who have travelled to endemic areas, intracerebral Chagas disease needs to be considered. VZV may cause a demyelinating syndrome with lateralizing features, and CMV has been reported to cause mass lesions.<sup>69</sup> It is interesting that HIV infection does not appear to significantly increase the risk for herpes simplex virus encephalitis, though HSV-2 infections may be encountered. Opportunistic infective granulomas in the basal ganglia may lead to extrapyramidal disorders, e.g., choreoathetosis, dystonia, hemiballismus, and

rarely, parkinsonism.<sup>70</sup> Chorea in AIDS has been described in toxoplasmosis, PML, and HIV encephalopathy.<sup>71</sup>

## SPINAL CORD DISORDERS

### HIV-Associated Myelopathy/Vacuolar Myelopathy (VM)

The spinal cord is most commonly affected in HIV infection. VM is unusual in the early stages of HIV disease but is relatively common in advanced infection. Autopsy studies have identified white matter changes in 20–55% of patients although clinical myelopathy is less common.<sup>72</sup>

VM affects 5–10% of untreated AIDS-defined patients, usually manifesting as gait ataxia, leg weakness, spasticity, and incontinence.<sup>73</sup> Impaired proprioception with sensory ataxia may also be seen as in subacute combined degeneration of cord or tabes dorsalis. Onset and progression is fairly insidious, with no back pain. Upper limb signs are less common, although hyper reflexia in the arms may occasionally be seen. There is no sensory level. Subclinical VM may be evident in otherwise asymptomatic patients with features such as hyper reflexia, spasticity, and extensor plantar response.

In the differential diagnosis for HIV-associated myelopathy, clinicians should exclude other treatable conditions that could cause spinal cord disease, particularly compressive lesions and other infectious or neoplastic etiologies. Conditions such as HTLV type I and II infection, vitamin B<sub>12</sub> deficiency, multiple sclerosis, varicella zoster associated myelopathy can present with similar features. Pott spine, intramedullary tuberculomas, toxoplasmosis, syphilis, and acute transverse myelitis also need to be considered. The most common mass lesion affecting the spinal cord is lymphoma. It may present as a compressive lesion, meningeal lymphomatosis or as epidural metastases. HIV-infected intravenous drug users may develop spinal epidural abscess caused by *S. aureus*, which is a neurosurgical emergency. Atypical mycobacteria, *M. avium* complex may also rarely cause spinal epidural abscess with presacral and piriformis muscle inflammation.<sup>74</sup> Cryptococcal myelitis with or without vertebral osteomyelitis has also been described.<sup>75</sup>

Tests such as complete blood counts with indices, vitamin B<sub>12</sub> levels and neuroimaging studies should be performed to rule out other and treatable causes of chronic myelopathies. Investigations such as serum RPR or VDRL, toxoplasma antibodies, cryptococcal antigen also need to be obtained. The neuropathologic correlates of VM are axonal injury and intense macrophage infiltration, which is found in over 50% of HIV/AIDS at autopsy. The vacuolar appearance primarily localized in the lateral and dorsal columns of thoracic spinal cord may reflect intramyelinic edema.<sup>76</sup>

Although HAART appears to reduce the incidence of VM, limited reversal of the signs or symptoms is observed after therapy is implemented. Symptomatic treatment (including baclofen and gabapentin) for painful spasticity, neurogenic bladder, clonus, and tremor is frequently beneficial to patients who have VM.

## NEUROPATHIES

HIV-1 infection is associated with a wide variety of peripheral neuropathy syndromes, with onset from the time of seroconversion to the late stages of AIDS.<sup>77,78</sup>

### Acute and Chronic Inflammatory Demyelinating Polyradiculoneuropathies

AIDP often occurs early in the course of HIV infection, particularly during seroconversion. It causes rapidly progressive weakness, with minor sensory symptoms and generalized areflexia. CIDP symptoms and signs are similar to acute IDP, except that CIDP is more slowly progressive (>6 weeks), has a more protracted course, and may be monophasic or relapsing. Blood studies should include serum lactate and bicarbonate to screen for hyperlactatemia. CSF analysis usually reveals elevated protein level with evidence of lymphocytic pleocytosis (10–50 cells/mm<sup>3</sup>) as opposed to seronegative patients where the characteristic albumino-cytological dissociation is evident. CSF-CMV PCR should be determined. Electrophysiological findings are consistent with demyelination. Plasmapheresis or intravenous immunoglobulin (IVIgG) is the preferred treatment for both acute and chronic inflammatory demyelinating polyneuropathies if the illness is sufficiently severe to warrant intervention.

### Mononeuropathy Multiplex

Mononeuropathy multiplex is relatively rare. It is characterized clinically by multifocal motor and sensory nerve abnormalities. These abnormalities have an asymmetric distribution. Tendon reflexes are preserved in uninvolved areas. Extensive nerve involvement may rapidly progress to include multiple cranial nerves. The occurrence is bimodal with the first peak at CD4+ >200 cell/mm<sup>3</sup> and the second peak at CD4+ 50–100 cells/mm<sup>3</sup>. It may be associated with herpes zoster, CMV, hepatitis C, syphilis, lymphomatous infiltration, or necrotizing vasculitis. Unilateral or bilateral facial palsy may accompany HIV-1 seroconversion. In those with CD4+ of <200, CMV infection is to be ruled out. If not demonstrated peripheral nerve vasculitis needs to be considered. Nerve biopsy studies reveal that Schwann cells may be infected directly by HIV-1 particles.<sup>79</sup> It is preferable to observe patients with early-onset MM because it may spontaneously resolve within weeks to several months. HAART may be initiated in patients with late-onset MM occurring in advanced HIV infection. In cases of delayed or incomplete recovery, corticosteroids, plasmapheresis, or IVIgG may be indicated.

### Progressive Polyradiculoneuropathy

This occurs most commonly in advanced HIV infection when CD4 cell counts decrease to <50 cells/mm<sup>3</sup>. Rapid onset of radiating pain and paresthesias in a cauda equina distribution followed by signs of progressive involvement of multiple nerve roots, usually lumbar and sacral is seen. Clinical signs include

flaccid paraparesis, sphincter dysfunction, and lower extremity areflexia. With the advent of HAART its incidence, particularly polyradiculopathy due to CMV, has markedly decreased. Contrast-enhanced MRI of the lumbar spine may reveal increased T2 signal of cauda equina and enhanced, thickened, and clumped lumbosacral roots. CSF is to be assayed for CMV, VZV, VDRL, and cytology. In CMV polyradiculopathy, CSF shows marked polymorphonuclear pleocytosis (>40% cells), elevated protein and hypoglycorrhachia. For most of the other etiologies mentioned, CSF reveals predominantly lymphocytic pleocytosis. EMG studies show reduced number of motor units and abnormal spontaneous activity in weak muscles. Nerve conduction velocities are only mildly abnormal. Prompt initiation of anti-CMV therapy may lead to improvement of symptoms or stabilization of signs in progressive polyradiculopathy secondary to CMV. Optimization of HAART in patients with progressive polyradiculopathy is necessary. Polyradiculoneuropathy secondary to CMV has 100% mortality when effective antiviral treatment is not given. Combination therapy with ganciclovir and foscarnet may provide efficacy, but no controlled data are available to support this.

Another condition associated with HIV-1 infection, diffuse infiltrative lymphocytosis syndrome, is a nonmalignant CD8 lymphocytosis that may affect multiple viscera as well as peripheral nerve and may respond to either corticosteroid or HAART.<sup>80</sup> Herpes zoster radiculitis can lead to ataxic sensory polyganglionopathy during seroconversion.

### HIV1-Associated Motor Neuron Disease (MND)

A retrospective review of 1700 cases of HIV-1 infected patients identified 6 cases presenting as a reversible ALS-like syndrome.<sup>81</sup> Younger age of onset (<40 years) was noted with a characteristic monomelic presentation involving adjoining segments of one limb followed by rapid spread. There were clinical features of both upper and lower motor neuron involvement. Rapidly progressive dementia was also noted in two patients. CSF was inconclusive while MRI revealed diffuse white matter signal intensities consistent with HAD. Electrophysiology revealed a widespread motor axonopathy. In each case HAART was beneficial in stabilizing the disease and in two cases curing it.

### Distal Sensory Polyneuropathy (DSP)

In advanced stages of AIDS, 25–38% of patients suffer from DSP.<sup>82</sup> DSP may occur secondary to HIV (HIV-DSP) or may be due to antiretroviral (ARV) drug toxicity (ARV-DSP). The clinical features of HIV-DSP and ARV-DSP are identical, with pain and paresthesias being the principal symptoms. Timely detection may allow for the reversal of the toxic effects of ARVs and for the initiation of symptomatic treatment.

The pathogenic mechanism of HIV-DSP is uncertain but likely multifactorial.<sup>83</sup> HIV-DSP tends to appear in advanced stages of HIV infection. It is thought that HIV disease progression

leads to dysregulation of macrophages and overproduction of proinflammatory cytokines and chemokines, which in turn leads to DSP. ARV-DSP is associated with the use of the NRTIs didanosine (ddI), zalcitabine (ddC), and stavudine (d4T). More recently, some protease inhibitors (PIs), including indinavir, saquinavir, and ritonavir, have also been implicated. These ARVs appear to have adverse effects on metabolism, with increased risk for mitochondrial toxicity. In many cases, ARV toxicity may unmask a previously asymptomatic HIV-DSP or may act synergistically with the pathogenic effect of HIV itself. Exacerbation by concomitant diabetes mellitus, alcoholism is often evident. The pathologic hallmark is distal axonal degeneration. Small-diameter nociceptive sensory axons and their respective soma in the dorsal root ganglion are the principal cellular structures affected.

Patients typically present with paresthesias, dysesthesias, and/or numbness in “stocking and glove” distribution and reduced deep tendon reflexes. Loss of proprioception and significant objective muscle weakness are atypical for DSP. ARV-DSP usually bears a temporal relationship to initiation of the drug. A history of symptom onset soon after the initiation of a potentially neurotoxic ARV, often within weeks, supports the diagnosis of ARV-DSP. Most important, symptoms improve or resolve within 8 weeks following dose reduction or drug cessation, although in some patients, a “coasting phenomenon” of increased symptoms may follow drug discontinuation before clinical improvement occurs. Incomplete resolution of symptoms and signs following cessation of neurotoxic drugs may be due to coexistent HIV-DSP. Patients who have any systemic polyneuropathy, including HIV- and ARV-DSP, may be at higher risk for superimposed entrapment neuropathies.

Blood studies should be performed to exclude other causes of DSP (e.g., glucose,  $B_{12}$ ). Electrophysiological studies reveal absence or reduction of sural nerve amplitudes. Nerve biopsy is rarely necessary in DSP, except in atypical cases. Skin biopsy with epidermal nerve fiber density studies is currently used in the research setting.<sup>84</sup>

The approach to treatment of DSP begins with eliminating neurotoxic ARVs when possible. In cases of ARV therapy-associated DSP, the decision to discontinue a neurotoxic ARV drug is not automatic and should only be made after carefully weighing the risks and benefits of virologic control versus neuropathic symptom control. Any coexisting risk factors identified during the patient's evaluation, such as other neurotoxic medications, diabetes mellitus, or impaired glucose tolerance, vitamin  $B_{12}$  deficiency, renal or liver impairment, thyroid dysfunction, or syphilis, should be addressed. Mild analgesics, including acetaminophen, aspirin, or other NSAIDs, with or without adjunctive agents (e.g., anticonvulsants, antidepressants, topical agents), are the first line of therapy for pain control. Successful treatment of pain requires combinations of therapies that have different mechanisms of action, an approach termed rational polypharmacy.<sup>85</sup> Experimental therapies include peptide T, acetyl-L-carnitine, recombinant human nerve growth factor and erythropoietin. Tricyclic antidepressants (TCAs) and

selective serotonin-norepinephrine reuptake inhibitors (SNRIs) are the two major classes of antidepressants used in the treatment of neuropathic pain. Because TCAs may cause sedation and other anticholinergic side effects, they are typically started as a single low evening dose, such as amitriptyline (10–25 mg), and titrated to efficacy as tolerated. Two agents of the SNRI class are available: duloxetine and venlafaxine. Duloxetine is generally well-tolerated. The most common side effect of duloxetine (nausea) can be ameliorated by starting treatment at 30 mg daily and increasing to the recommended dose of 60 mg daily up to 120 mg daily after approximately 1 week. Anticonvulsants used include pregabalin (75–300 mg/day) and gabapentin (600–2400 mg/day). The vanilloid receptor agonist capsaicin interacts with C-fiber polymodal nociceptors. Epidermal nerve fibers have been shown to be capsaicin sensitive nociceptors. A 30- to 90-minute application of high-dose topical capsaicin patch, approximately once every 3 months, has shown significant pain relief in HIV-DSP.<sup>86</sup> Side effects include mild irritation, erythema, or burning pain at the application site. Mild opiates such as low-dose codeine, hydrocodone, and propoxyphene, usually in combination with NSAIDs, are used for moderate pain; more potent opioids including morphine, oxycodone, fentanyl, and methadone are used for severe pain.<sup>87</sup> There has been recent interest in more rapid-onset treatments for breakthrough pain in chronic pain syndromes such as HIV-DSP. Recent data show efficacy for an oral effervescent form of fentanyl in several forms of neuropathic pain.<sup>88</sup>

## MYOPATHY

Myopathic symptoms can arise from toxic (zidovudine) or dysimmune (polymyositis) causes or from AIDS cachexia (muscle wasting syndrome).<sup>89</sup> HIV-associated myopathy or polymyositis presents with slowly progressive weakness of proximal muscles and myalgias. Neurological examination reveals symmetric weakness of proximal muscles of the extremities and neck flexors. Deep tendon reflexes are intact unless there is superimposed peripheral neuropathy or myelopathy. On occasion it may be associated with immune restoration during HAART.<sup>90</sup> CPK levels are usually elevated (approx. 500 U/mL). Electromyography shows muscle irritability with abnormal spontaneous activity and myopathic features. Muscle biopsy reveals myofiber atrophy, often with associated endomysial inflammatory infiltrates. HIV does not appear to directly infect muscle fibers, but rather induces them to express major histocompatibility complex I, triggering cell-mediated muscle fiber injury. Inclusion body myositis has also been reported.<sup>89</sup> Although corticosteroids may provide benefit in HIV myopathy, they should be used with caution because of their immunosuppressant effects. Intravenous immunoglobulin is an alternative. Some patients with myopathy improve when zidovudine or other nucleoside ARV drugs are discontinued, but most do not.

HIV-associated neuromuscular weakness syndrome (HANWS) is commonly associated with the use of d4T. It is characterized by progressive weakness that develops over days to weeks and

may progress to respiratory failure and death.<sup>91</sup> Lactic acidosis or hyperlactatemia is often present. Electrophysiologic studies reveal axonal neuropathy or myopathy. Other common peripheral neuropathies associated with comorbidities also need to be excluded, including diabetes mellitus, hypothyroidism, nutritional deficiency, excess ethanol consumption, hepatitis B or C virus or syphilis infections, and other drug-related conditions.

Zidovudine myopathy is due to mitochondrial toxicity,<sup>92</sup> especially in doses of >1000 mg/day on monotherapy or lesser doses on HAART. At least 6 months of exposure to the drug is necessary. Proximal weakness and myalgia are presenting features. Clinical response to a drug holiday or reduction in dose often obviates the need for biopsy.

Pyomyositis can present as a focal suppurative myositis with fever, local muscle pain and swelling and bacteremia.<sup>93</sup> It is commonly caused by *Staph. aureus*, *Salmonella spp.* or gram-negative bacilli. Surgical drainage followed by intravenous antibiotics for 1–2 weeks and then oral therapy for up to 8 weeks is necessary. Disseminated infection with *Cryptococcus*, *Toxoplasma*, *M. tuberculosis*, *M. avium intracellulare*, and microsporidia may also involve muscle.

## Neurologic Immune Reconstitution Inflammatory Syndrome (IRIS)

As immunologic improvement begins with suppression of the viral load in blood and as the patient's CD4+ T cell count rises, the clinical deterioration occurs, usually within weeks of ART initiation, although IRIS has been recognized months after ART was started. The mechanism of clinical deterioration during IRIS is thought to be sudden activation and increase in CD4 T cells (specifically CD45RO memory cells), resulting in a heightened immune response and significant host-mediated inflammatory cell damage.<sup>94</sup> The onset of neurologic signs and symptoms or worsening of prior neurologic disabilities is often apparent in patients who have very low CD4 T-cell counts and concurrent CNS opportunistic infections<sup>95</sup> after HAART is introduced; this syndrome is termed neurologic IRIS (neuro IRIS). The underlying opportunistic infection may be active, although in some cases, it is subclinical and does not manifest itself until after HAART is initiated.<sup>96</sup> Across most studies,<sup>97</sup> approximately 20–25% of patients started on cART develop some form of IRIS, whereas the risk of neuro IRIS is substantially lower. On average, 60% of patients who develop IRIS present within 60 days of initiating cART, although its presentation can be biphasic, with onset within 30 days of initiating cART or after 90 days.<sup>98</sup> Neuro IRIS results in focal CNS deficits including encephalopathy, hemiparesis and seizures, CSF pleocytosis, and white matter and cortical abnormalities in neuroimaging, and is frequently observed in the context of pre-existing progressive multifocal leukoencephalopathy, cryptococcal meningitis, cytomegalovirus retinitis, and occasionally HAD. Neuropathologic studies of neuro IRIS disclose widespread leukocyte (lymphocyte and macrophage) infiltrates in the brain, frequently proximate to the pre-existing infection.<sup>99,100</sup> The extent of neurologic disability varies widely but may respond to treatment with glucocorticoids,

although the full extent of neuro IRIS in terms of epidemiology and underlying pathogenesis warrants further study.

## Conclusions

More than half of HIV-infected patients develop symptomatic neurological disease. The nervous system is extensively involved with no part of the neuraxis being immune from the virus. Neurological complications typically occur with advanced disease and profound immunosuppression.<sup>101</sup> Since many of the conditions are amenable to treatment, a proper diagnosis and therapy may decrease morbidity in the already curtailed life span of the patient. The aim of the physician should be to unmask the neurological disorder from a host of symptoms keeping in mind that there is “layering” or “parallel tracking” of various etiologies in HIV neurology.

## Introduction

Gastrointestinal and hepatobiliary symptoms are among the most frequent complaints in patients with human immunodeficiency virus (HIV) infection and AIDS, developing anytime during the course of the illness. These include a wide-spectrum of illnesses, some caused by HIV itself but more often caused by opportunistic infections and neoplasms. They present difficult diagnostic and management challenges to the treating physicians, who may have to use their acumen and a wide battery of laboratory investigations to identify the vast number of potential infections, neoplasms, and consequences of treatment of HIV. Involvement of different organs of gastrointestinal tract in HIV-infected individuals is discussed below.

## Oropharyngeal Manifestations

Oropharyngeal manifestations are common in patients with HIV infection. They cause significant morbidity and also provide diagnostic clues to the underlying immunocompromised status. These may be a reason for referral and investigation for HIV infection.<sup>1-5</sup> Oral pathologies can occur in up to 80% patients infected with HIV. The most common complaint is thrush (oropharyngeal candidiasis). It may be an early indication of a suppressed immune status, but is not a good predictor of the severity of immunosuppression. It typically appears as white curd like patches or as an atrophic white or red friable lesion on the mucosal surface.<sup>1-5</sup> It is only a modest predictor of underlying esophageal candidiasis. Oral candidiasis is subdivided into the following categories: pseudomembranous candidiasis (thrush), erythematous candidiasis, angular cheilitis, and hyperplastic candidiasis (leukoplakia).<sup>1-5</sup> Pseudomembranous candidiasis is the most commonly recognized form and is characterized by whitish plaques throughout the oral cavity. The erythematous form presents as reddish lesions on the palate or dorsum of the tongue. Angular cheilitis is recognized as red, flaking lesions at the corners of mouth. Hyperplastic candidiasis is the least common presentation in HIV infection and is characterized by easily identified thick, white plaques on mucosa. The diagnosis is frequently made on clinical grounds but confirmation can be

achieved by demonstration of pseudohyphae on KOH smears. Topical treatment with nystatin (100,000 IU Tab 3–5/day) or clotrimazole (10 mg troches/lozenges) is generally effective. In patients with associated esophageal candidiasis, systemic treatment with fluconazole (100–200 mg daily for 7–14 days) is preferable. The problem is one of frequent recurrences and need for repeated courses of treatment.

Individuals infected with HIV commonly develop oropharyngeal ulcers. The prevalence has been suggested to be around 10%.<sup>2-5</sup> Possible causes include (i) viruses such as herpes simplex virus (HSV), reactivated varicella zoster virus, and cytomegalovirus (CMV); (ii) immunologic causes such as aphthous ulcers; and less commonly (iii) fungal infections such as histoplasmosis.<sup>4-9</sup> Herpes simplex and dermatomal varicella zoster reactivation (shingles), commonly involve the perioral skin and sometimes the oral mucosa also. They present as small, very painful vesicles and ulcers. Cytomegalovirus and aphthous ulcers may appear similar to varicella zoster and HSV infection clinically, but both lack a prodrome. Cytomegalovirus is distinguished by the presence of intranuclear or intracytoplasmic inclusions seen on microscopic analysis. Confirmation can be obtained with immunohistochemistry.<sup>9-10</sup> Histoplasmosis lesions begin as flat, nontender plaques that then evolve to painful ulcers. Scraping of the lesions for fungal culture is helpful to confirm the diagnosis.

Other oral lesions associated with HIV infection include neoplastic growths such as human papillomavirus (HPV) infection, lesions of Kaposi sarcoma, and lymphomas.<sup>9-18</sup> HPV infection may present as condyloma acuminata, or focal epithelial hyperplasia. Simple surgical excision is usually curative.

The prevalence of oral hairy leukoplakia (OHL) has been found to range from 18% to 23% in HIV-infected patients.<sup>2-4</sup> It appears as corrugated white lesions almost always on the lateral borders of the tongue. It is usually asymptomatic and may appear early in the course of the illness, but there is no correlation with stage of the disease. Confirmation by histopathological examination is required for the diagnosis and oral candidiasis is to be ruled out. The presence of oral hairy leukoplakia is a

harbinger for disease progression; 48% of patients with oral hairy leukoplakia develop AIDS diagnosis within 16 months, and 83% develop an AIDS diagnosis within 31 months. As it is usually asymptomatic, treatment is empirical or elective and includes acyclovir, topical retinoic acid, and local application of podophyllin.

Although Kaposi sarcoma more commonly presents on the skin, the hard palate, gingiva, buccal mucosa, dorsum of tongue, and nasal mucosa can be involved. Mucosal Kaposi sarcoma appears as a red to purple raised plaque, which can ulcerate. More frequently than cutaneous Kaposi sarcoma, mucosal Kaposi sarcoma presents with pain, ulceration, and bleeding.<sup>5-9</sup> Mucosal Kaposi sarcoma is usually accompanied by concurrent cutaneous lesions. Treatment focusses on local control of symptoms and may include excision, external-beam radiation, and vinblastine injection.

Other conditions include recurrent aphthous ulcerations, chronic mucocutaneous HSV infection and bartonellosis. Severe periodontal disease and alveolar bone loss is also frequent. Drug reactions and Stevens–Johnson syndrome have become more frequent with the advent of antiretroviral drugs.

## Esophageal Disorders

Esophageal symptoms occur in one-third of the patients with AIDS. Esophagitis is associated with a poor prognosis, with untreated patients having a mean survival time of 5 months.<sup>1-6</sup> The most common symptoms of esophageal disease include odynophagia, dysphagia, and retrosternal chest pain. The presence of a particular symptom is not indicative of any specific etiology although infection with candida is most common.<sup>2-6</sup> Other symptoms include bleeding from the ulcer(s), coughing, and aspiration from the bronchoesophageal fistula.<sup>6-9</sup> Esophageal disease can be divided broadly into three etiologic groups: infections, neoplasms, and others noninfectious, non-neoplastic causes.

### INFECTIONS

Candida is the most common esophageal pathogen in AIDS, followed by viral diseases.<sup>1-6</sup> In the era of highly active antiretroviral therapy (HAART), many of the previously common HIV-related infectious disorders have essentially vanished. Nevertheless, these opportunistic disorders can be observed in patients who are failing HAART (low CD4, high viral load) or who are noncompliant.

Patients with a CD4 count <200 cells/mL are those at greatest risk for opportunistic infections (Table 77.1). Also, the risk of candidiasis rises exponentially with a fall in CD4 cells <100 cells/ $\mu$ L. Candida esophagitis rises in incidence at a CD4 count of 100–200  $\mu$ L, whereas *Mycobacterium avium* complex is very uncommon until the CD4 count falls below 50.

### Candida Albicans

Candida is the most frequent cause of fungal esophagitis occurring in 42–79% of patients.<sup>1-6</sup> In the immunocompromised patient, colonization becomes more widespread and may be followed by

**Table 77.1:** Correlation of CD4 Cell Count and Gastrointestinal Infection

CD4 cell count	Common infections
CD4 <50 cells/ $\mu$ L	<i>Mycobacterium avium</i> complex Cryptococcus <i>Penicillium marneffei</i> Cytomegalovirus
CD4 <100 cells/ $\mu$ L	Cryptosporidium species Microsporidium species <i>Leishmania donovani</i>
CD4 <250 cells/ $\mu$ L	<i>Histoplasma capsulatum</i> <i>Coccidioides immitis</i>
At any level of CD4 cell count	<i>Clostridium difficile</i> Salmonella Shigella <i>Campylobacter jejuni</i> <i>Isospora belli</i> <i>Mycobacterium tuberculosis</i> <i>Cyclospora cayetanensis</i> <i>Strongyloides stercoralis</i> <i>Ancylostoma duodenale</i>

epithelial or deeper invasion into the mucosa and submucosa.<sup>2-6</sup> Endoscopic appearance is characterized by creamy yellowish white plaques overlying erythematous base (Fig. 77.1a,b,c). Plaque removal may reveal underlying erosion and mucosal friability. Other fungi causing esophagitis include *Torulopsis glabrata*, *Histoplasma capsulatum*, and *Aspergillus*.

### Cytomegalovirus (CMV)

It is the most common viral infection accounting for 45% of all esophageal ulcers on endoscopy in HIV-positive patients.<sup>2-9</sup> It is almost always associated with odynophagia and CD4 counts are usually less than 120 cells/ $\mu$ L. The majority of the CMV lesions are located in the middle (57%) and distal third (32%) of the esophagus. Ulcers are usually greater than 1 cm in size (giant esophageal ulcers), and in another 28% of cases they are greater than 2 cm.<sup>9,10</sup> In 8% of the patients, the ulcers may be deep, and in about 58% patients they may be multiple. Lesions may also

**Fig. 77.1a:** Yellowish-white plaques of Candida esophagitis at endoscopy.

**Fig. 77.1b :** Low power photomicrograph of an esophageal biopsy showing a deep mucosal ulcer with necrotic ulcer bed (H&E,  $\times 45$ ). *Courtesy:* Dr. Kim Vaiphei, Professor of Pathology, PGIMER, Chandigarh.

**Fig. 77.1c:** High power photomicrograph of the same to show multiple fungal pseudohyphae and budding yeasts of *Candida*, seen in bright magenta color (PAS,  $\times 450$ ). *Courtesy:* Dr. Kim Vaiphei, Professor of Pathology, PGIMER, Chandigarh.

appear as heaped up ulcers and/or as large exophytic lesions. Complications include strictures and bacterial superinfection.<sup>9–11</sup>

As CMV infects stromal cells, multiple biopsies must be taken from the center of the ulcer. The diagnosis of gastrointestinal CMV infection is best established by demonstrating viral cytopathic effect in tissue specimens. The inclusions may be atypical in appearance or few in number, requiring immunostaining and/or *in situ* hybridization for confirmation. Biopsies can also be subjected to viral culture or PCR.

### Herpes Simplex Virus (HSV)

It is a common infection found when CD4<sup>+</sup> count is 150 cells/ $\mu$ L or less. The complaints include dysphagia (86%), odynophagia (82%), chest pain (68%), fever (44%), nausea, vomiting, and rarely hematemesis.<sup>13–20</sup> Associated herpetic

**Fig. 77.2:** Endoscopic picture of HSV esophagitis.

lesions on the nasolabial region may suggest the diagnosis in a patient presenting with dysphagia and odynophagia. The earliest lesions are 1–3 mm rounded vesicles in the middle to distal esophagus, which slough and form small discrete punched out (volcano) ulcers. Later, the ulcers coalesce and develop an overlying white or yellow pseudomembrane, mucosal friability, and plaque formation (Fig. 77.2). Complications include mucosal necrosis and super-infection, hemorrhage, stricture, HSV pneumonia, tracheoesophageal fistula, hiccups, and disseminated HSV.<sup>13–20</sup>

Staining of HSV-infected epithelial cells demonstrate multinucleated giant cells, ballooning degeneration, “ground glass” intranuclear Cowdry type A inclusion bodies, and margination of chromatin. Immunohistochemical staining may make the diagnosis of HSV in tissues easier. HSV may be cultured from esophageal tissue which may also be subjected to PCR; both are more sensitive than routine histology or cytology.

Herpes esophagitis can be treated with a 7–10-day course of orally administered acyclovir or valacyclovir. With severe odynophagia or in very sick patients, treatment can be started with intravenous acyclovir, 250 mg/m<sup>2</sup> every 8 hours and then changing to oral therapy when the patient can take oral medication.

### HIV

Whether or not the presence of HIV-infected cells in the alimentary tract leads to symptoms is debatable. In patients with esophageal symptoms, HIV-1 mRNA was detected in 36% of the patients. Esophageal ulcers are found during seroconversion, with a finding of randomly distributed single or multiple ulcers, which are round or oval 3–15 mm in diameter with distinct margins and surrounding normal mucosa.<sup>15–20</sup> These clinical and pathologic findings resolve over a period of 2 weeks.

### Mycobacteria

Mycobacteria including *M. tuberculosis* and *M. avium* complex can cause diffuse irregularity of the mucosa, mucosal ulcers, sinus tracts, and tracheoesophageal and esophagobronchial fistulae.<sup>6</sup>

## NEOPLASTIC DISEASES

Neoplastic diseases are highly unusual in the esophagus in patients with AIDS. The most common neoplasm of the esophagus is Kaposi sarcoma, seen in 16% of the patients.

## NONINFECTIOUS, NON-NEOPLASTIC CAUSES OF ESOPHAGEAL LESIONS

### Drug-Induced Esophagitis

Patients are at risk for pill induced esophagitis due to the numerous drugs that they take and many have an underlying motility disorder.<sup>19</sup> The offending drugs include doxycycline, potassium preparations, NSAIDs, zidovudine, and zalcitabine. Gastroesophageal reflux (GER) disease is quite uncommon in this group as many patients have achlorhydria.

### Idiopathic Esophageal (Aphthous) Ulcers

This term describes ulcers in HIV-infected individuals in whom no cause is identified despite a thorough histopathological examination of the tissue. The clinical picture is one of odynophagia, substernal chest pain, and little or no relief with narcotics or analgesics. Average CD4 counts are usually <50 cells/ $\mu$ L.<sup>9</sup> Giant esophageal ulcers are common.<sup>9</sup> The postulated mechanism is overproduction of cytokines, especially interleukin (IL)-1, IL-6, and arachidonic acid metabolites. This is evidenced by a good response to thalidomide 200 mg/day which inhibits cytokine tumor necrosis factor- $\alpha$  (TNF- $\alpha$ ) and also inhibits angiogenesis.<sup>20,21</sup>

## MANAGEMENT OF ESOPHAGEAL DISEASES

Recent data have suggested a role for empirical use of fluconazole 100 mg PO for 7 days in patients with mild to moderate symptoms of recent onset. It results in improvement in 78% of the patients, as *Candida* is the most common organism found in this subset of patients.<sup>20,21</sup> Patients with severe symptoms, (e.g., inability to eat), or with a suspected complication, (such as a fistula) should undergo early endoscopy and biopsy. Such patients should be treated with 400 mg/day of fluconazole. Recurrent esophageal candidiasis is almost universal; however, long-term prophylaxis is expensive and carries the risk of resistance.<sup>22-24</sup>

Cytomegalovirus responds to either ganciclovir or foscarnet (response rate 85% vs. 83%), but both are ineffective in preventing recurrences. Regardless of the regimen used, relapse occurs in 39% of complete responders not on maintenance therapy.<sup>23,24</sup> Herpetic esophagitis responds to acyclovir at a dose of 15–30 mg/kg/day IV/orally. Valacyclovir and famciclovir are preferred by some because of less frequent dosing and better absorption.<sup>22-24</sup> Prednisolone in a dose of 40 mg/day and tapered by 10 mg/week has been tried for idiopathic aphthous and esophageal ulcers. One promising new therapy for this is thalidomide 200 mg daily for 2 weeks.<sup>21,24</sup>

## Gastroduodenal Diseases

Gastroduodenal ulcers are infrequent in HIV-positive subjects.<sup>25-28</sup> CMV is the only organism significantly associated with gastroduodenal ulcerations, and *Helicobacter pylori* is an uncommon cause of ulcers.<sup>24</sup> Chronic active gastritis is more common and is associated with pathogens other than *H. pylori*.<sup>24</sup> This also explains the low prevalence of low-grade gastric mucosa associated lymphoid tissue (MALT) lymphomas in HIV-positive patients.<sup>25</sup> Hypochlorhydria is common and occurs early in the course of HIV disease. Abnormal secretory function of the parietal cells affects acid as well as intrinsic factor secretion. It is associated with morphological changes in acid secretory apparatus.<sup>26,27</sup> HIV-associated visceral neuropathy may be present in the relatively late stages of infection and may contribute to abdominal symptoms like dyspepsia, dysphagia, vomiting, and nausea that frequently occur in these individuals. This is evidenced by faster gastric emptying rate of liquids and significantly delayed emptying of solids.<sup>26-28</sup>

## Diarrheal Diseases

Diarrhea is one of the most common manifestations of HIV infection. Substantial diarrhea occurs in about 50% of the HIV-infected individuals in developed countries and the corresponding figure for developing and underdeveloped countries may be as high as 80%.<sup>29-34</sup> The most common cause of diarrhea in this population remains opportunistic infections but the rate of isolation of a specific pathogen depends on the extent of diagnostic work up carried out on these patients.<sup>32-36</sup> With exhaustive and intuitive evaluation, specific enteric pathogens can be isolated in most patients with severe diarrhea. Diarrhea leads to a diminished quality of life. Clinical presentation of HIV-associated diarrhea depends on the principal area of the gut involved. Small-bowel type of diarrhea tends to produce large, bulky, postprandial stools. These patients commonly have postprandial periumbilical pain and significant weight loss. In contrast, predominant large bowel involvement results in more frequent but small volume stools which may contain visible amounts of blood and mucus. Dehydration is uncommon with only large bowel type of diarrhea and location of pain, if present, is lower abdomen. Chronic diarrhea is an independent marker of poor prognosis in patients with AIDS.

### CAUSES OF DIARRHEAL ILLNESSES (TABLE 77.2)

A definite cause for diarrhea can be identified in 50–80% of patients with AIDS. In the remaining 20%, no clear cause is evident.<sup>30-36</sup> The other proposed mechanisms include direct effect of HIV, altered intestinal permeability, bile acid malabsorption, dysregulation of enteric immune system, local production of lymphokines, and autoimmune denervation.<sup>30-36</sup>

In the era of HAART, opportunistic infections causing diarrhea have fallen dramatically.<sup>30-34</sup> Experience at a single center between

1995 and 1997 found that the occurrence of chronic diarrhea remained constant (8–10% per year) for those with CD4 counts <200 cells/ $\mu$ L. Opportunistic infections with HAART fell drastically from 53% to 13%, while other infections unrelated to immunodeficiency rose.<sup>30–33</sup> The proportion of patients diagnosed with noninfectious causes increased from 32% to 70% over the 3-year period. Diarrhea may be caused by a number of drugs in the patients infected with HIV. Drug-induced diarrhea has been frequently attributed to protease inhibitors, and studies suggest that diarrhea occurs in up to 50% of patients taking nelfinavir and in up to 20% of those taking lopinavir/ritonavir and fosamprenavir/ritonavir.<sup>36–39</sup> Often there is a temporal association between drug initiation and diarrhea, and typically diarrhea is of mild to moderate severity.

A search for typical HIV-associated processes should be undertaken based upon risk stratification of the patient. Patients with severe immunodeficiency (CD4 count  $\leq$ 100 cells/ $\mu$ L) are those most at risk for cryptosporidium, microsporidium, and CMV disease. *Mycobacterium avium* complex, commonly seen in the pre-HAART era, is now very rare and is most likely to be found in the patient who first presents with end-stage HIV infection. *Mycobacterium tuberculosis* can involve the gut and is an important cause of disease in AIDS patients in the developing world. The same is true for *Giardia lamblia* (Fig. 77.3).

**Fig. 77.3:** Photomicrograph of duodenal biopsy from a patient who presented with chronic diarrhea showing intact surface epithelium with clusters of pear to sickle shaped *Giardia lamblia* trophozoites (H&E,  $\times$ 450). Courtesy: Dr. Kim Vaiphei, Professor of Pathology, PGIMER, Chandigarh.

## Specific Infections

### CRYPTOSPORIDIUM

*Cryptosporidium parvum* is the species that infects both humans and cattle. The modes of transmission are water contamination and direct feco-oral route. *Cryptosporidium parvum* primarily inhabits the microvillous border of intestinal epithelial cells. Its oocysts are highly environmentally resistant. As cell-mediated immunity declines to CD4 count less than 180 cells/mL, patients develop chronic, heavy cryptosporidial infection.<sup>30–33,39–41</sup> The ileum and jejunum are primary sites of infection with vitamin B12, and d-xylose malabsorption occurring due to villous atrophy and altered permeability.

In immunocompetent persons, cryptosporidiosis is a self-limited diarrheal illness with an incubation period of 7 days and a mean duration of 12 days. In immunodeficient HIV-infected individuals, however, infection may be prolonged. The diarrhea is non-bloody and may be associated with nausea, vomiting, and abdominal cramps. Patients with CD4 cell count of >180/ $\mu$ L tend to clear the infection. Four patterns of infection have been described among the HIV-infected patients: (i) asymptomatic (4% of patients); (ii) transient symptomatic (28%), which spontaneously resolved within 2 months; (iii) chronic (60%), which persisted for at least 2 months; and (iv) fulminant (8%), which was refractory to therapy and was characterized by the passage of 2 liters or more of liquid stool daily.<sup>30–33,39–41</sup> Biliary and respiratory tract involvement can occur in advanced AIDS. Biliary manifestations include acalculous cholecystitis, sclerosing cholangitis, or pancreatitis, which usually presents with right upper quadrant abdominal pain.

**Fig. 77.4:** Photomicrograph of duodenal biopsy from a patient with long standing small bowel diarrhea showing mild inflammation of the lining epithelium with many small spherical bodies seen as reddish structures (cryptosporidia) on Masson trichrome staining ( $\times 450$ ). Courtesy: Dr. Kim Vaiphei, Professor of Pathology, PGIMER, Chandigarh.

Cryptosporidial oocysts can be shown in stool samples using either a modified acid-fast stain or a commercially available kit based on an immunofluorescence technique. The organism can also be detected using light-microscopic examination of duodenal (Fig. 77.4) or, less commonly, colonic mucosal biopsy specimens. Diagnosis is by stool examination using modified acid-fast stain and microscopy or enzyme-linked immunosorbent assay (ELISA).

Nitazoxanide and paromomycin are the two drugs which have been shown to be effective in treatment of diarrhea caused by cryptosporidium. In clinical trials, overall 59% of patients treated with nitazoxanide achieved a clinical response with culture-negative stools while on nitazoxanide therapy; patients with higher CD4 counts were more likely to achieve a continued clinical response.<sup>30–33,40–48</sup> Variable response rate has been reported with paromomycin. Paromomycin might result in some clinical improvement in patients with cryptosporidial diarrhea, but these improvements were short lived and associated with a high relapse rate, approaching 33% once therapy was discontinued. There is paucity of data comparing the efficacy of nitazoxanide and paromomycin. Current evidence strongly supports the use of HAART as initial therapy for patients with cryptosporidiosis; HAART clearly has shown consistent clinical effects and the ability to cure parasitic infections in many HIV-infected patients. For patients who continue to have severe diarrheal disease despite HAART and improved CD4+ T-cell function, the addition of nitazoxanide therapy should be considered. However, nitazoxanide therapy alone is inappropriate without HAART.<sup>30–33,39–41</sup>

Other agents tried includes clarithromycin, octreotide, atovaquone, spiramycin, bovine dialyzable leukocyte extract, and bovine hyperimmune colostrums and rifaximin either as single agent or in various combinations but the published experience is very limited and efficacy usually limited and variable.

## MICROSPORIDIA

These are obligate intracellular spore producing microorganisms, now classified as fungus, that commonly cause chronic diarrhea, malabsorption, and wasting. *Encephalitozoon intestinalis* and *Enterocytozoon bieneusi* are the two most prevalent species encountered in immunocompromised patients. About 90% infections are due to *Enterocytozoon bieneusi*, which is found in 15–34% of AIDS patients with chronic diarrhea.<sup>30–33,49–57</sup> Symptomatic patients have CD4+ cell counts less than 100 cells/ $\mu$ L and present with multiple nonbloody, nonmucoid stools, abdominal discomfort, and occasionally vomiting but no fever. The infection is greatest in proximal jejunum resulting in villous atrophy and crypt hyperplasia leading to malabsorption. The organisms are round, 1–2 micron in diameter and are seen on duodenal biopsies with modified trichrome stain and fluorochrome calcofluor (Fig. 77.5). They are present at the apical cytoplasm of the villous enterocytes and contain prominent clefts.<sup>49–57</sup>

Antiretroviral therapy is of paramount importance in treating HIV patients who have microsporidium infections. HAART alone can result in cessation of diarrhea, considerable weight gain in wasting patients, and even a complete eradication of the organism. *Encephalitozoon intestinalis* infection consistently responds to albendazole. Albendazole inhibits tubulin polymerization and may even result in complete eradication of *Encephalitozoon intestinalis* infection in HIV-positive patients. In contrast, treatment of *Enterocytozoon bieneusi* infection is more difficult and challenging. Albendazole has limited efficacy against *Enterocytozoon bieneusi*.

**Fig. 77.5:** Photomicrograph of the duodenal biopsy showing crypts with mild increase in intraepithelial lymphocytes of the lining epithelial cells. The goblet cells are seen containing small round to oval uniform size hematoxyphilic bodies of Microsporidium (H&E,  $\times 450$ ). Courtesy: Dr. Kim Vaiphei, Professor of Pathology, PGIMER, Chandigarh.

infection and suppression is often incomplete and inconsistent. Fumagillin, an antibiotic with antiangiogenic properties, showed encouraging results in early studies in improving HIV symptoms and fecal clearance of the organism. A host of other agents have been tried, mostly with limited success. These agents include nitazoxanide, atovaquone, itraconazole, metronidazole, octreotide, thalidomide, and trimethoprim/sulfamethoxazole.

### ISOSPORA BELLI

It is clinically associated with less severe diarrhea. The prolonged gastrointestinal disease caused by it resembles mild cryptosporidiosis. It invades the proximal small intestine. The diarrhea is profuse, watery, nonbloody, and is associated with abdominal cramping.<sup>30–33</sup> On intestinal biopsy, acid-fast oocysts, measuring 20–30 micron, are seen within the bowel lumen or in cytoplasmic vacuoles in enterocytes with surrounding inflammation.<sup>54–57</sup>

Trimethoprim/sulfamethoxazole (160/800 mg) given orally 4 times a day for 10 days is the currently preferred initial therapy for this condition.<sup>30–33</sup> Although the initial response rate is fair, but relapses are common, particularly among the patients for whom HAART cannot be started or when CD4+ T-cell counts continue to remain less than 200 cells/ $\mu$ L. Due to high recurrence rate, secondary prophylaxis may be required, especially among the subjects who continue to have CD4 cell count <200 cells/ $\mu$ L. Ciprofloxacin nitazoxanide and pyrimethamine are the other agents which are useful in the treatment of this condition.

### CYCLOSPORA CAYETANENSIS

It is an acid-fast coccidian seen in AIDS patients when the CD4 counts decline to less than 50 cells/ $\mu$ L.<sup>30–37</sup> It causes prolonged watery diarrhea, anorexia, fatigue, nausea, bloating, and weight loss. There may be involvement of biliary tract. Cyclospora is seen as acid-fast, round oocysts, 9–10 micron in diameter as nonrefractile hyaline spheres containing globular inclusions in unstained smears.<sup>54–57</sup> The other protozoa seen, more in homosexual individuals, are *Entamoeba histolytica*, *Giardia lamblia*, and *Blastocystis hominis*.<sup>48</sup>

Treatment of cyclospora infection, including the indications for starting secondary prophylaxis is similar to isospora infection. The preferred therapy for cyclospora infection is trimethoprim/sulfamethoxazole (160/800 mg) orally 4 times a day for 7 days. Ciprofloxacin and nitazoxanide are the other useful drugs to treat this infection but their efficacy may be lower. Secondary prophylaxis may be required in those with very low CD4 cell count.

### CYTOMEGALOVIRUS

In patients with HIV infection, the source of CMV disease is either reactivation or reinfection because most individuals have been previously exposed to the virus. In a cohort study of patients with AIDS or symptomatic HIV infection followed up for 2 years, the cumulative probability of developing CMV disease was 21% for those with initial CD4 counts of 100/ $\mu$ L or less. Nearly 15%

of CMV infections occur in the GI tract and the prevalence of CMV colitis in HIV patients with diarrhea ranges from 13% to 45%.<sup>30–33,58–62</sup> CMV disease may involve any site of GIT, but it most often affects the small and large intestines but can also cause duodenal ulcers, enteritis, and ileocaecal perforation.<sup>30–33,61,62</sup> It is a major cause of morbidity and mortality in immunocompromised patients. Most patients experience intermittent or persistent diarrhea, cramping, lower abdominal pain, tenesmus, and weight loss. Patients are often febrile reflecting the invasive nature of the disease and also have anorexia, malaise, and rebound tenderness. It can also present as massive lower gastrointestinal bleed and pseudotumoral mucosal lesions. The possible mechanism of enteritis is CMV-induced vasculitis leading to thrombosis and occlusion of submucosal vessels causing ischemia. Clinical CMV disease occurs when the CD4 counts decline to less than 100/ $\mu$ L. As colitis progresses, full thickness of the bowel wall ulcerates and ultimately perforates. This and obstruction of the gut due to CMV is responsible for one-third of all abdominal surgeries required in AIDS patients.<sup>59–60</sup> On endoscopy, the mucosa is diffusely erythematous and friable with submucosal hemorrhages and mucosal ulcerations (Fig. 77.6a,b). Ulcers are discrete, round, or serpiginous and have a clean base. In one study, 41% had localized

Fig. 77.6a: Colonoscopic view of CMV colitis.

Fig. 77.6b: Photomicrograph of colonic biopsy colitis showing a part of atrophic surface epithelium with granulation tissue underneath. Many cytomegaly cells are seen interspersed with other inflammatory cells. Some of the cytomegaly cells have with intra-nuclear inclusion surrounded by a clear hallow around. (H&E,  $\times 450$ ). Courtesy: Dr. Kim Vaiphei, Professor of Pathology, PGIMER, Chandigarh.

patchy colitis, 34% had diffuse colitis, and 25% had normal mucosa.<sup>62</sup> There is a high percentage of right colonic disease, which highlights the importance of performing colonoscopy and taking biopsy samples from ascending, transverse, and descending colon. On hematoxylin and eosin (H&E) stain, characteristic changes include eosinophilic intracytoplasmic inclusion bodies surrounded by clear halos.

CMV infection of the GI tract should be treated with either ganciclovir or foscarnet for 3–6 weeks.<sup>30–33,37,38</sup> Duration of therapy can vary and depends on clinical resolution of signs and symptoms. Another emerging option to this essentially parenteral therapy is oral valganciclovir unless symptoms prevent a patient from taking oral medications and/or if symptoms are severe enough to result in intestinal malabsorption and thus decrease drug bioavailability. Both ganciclovir and foscarnet have been shown to lead to improvement in clinical symptoms, resolution of endoscopic findings, and disappearance of inclusion bodies on biopsy. Role of maintenance therapy remains uncertain and benefits in the setting of CMV infection of GIT have not been clearly defined. However, maintenance therapy may be considered if patients continue to have symptoms despite a complete course of therapy or if a patient has recurring disease. The need for maintenance therapy may be negated with the introduction of HAART. The appropriate time for initiating HAART in patients with GI CMV disease is a source of controversy. Given the theoretical risk of developing immune reconstitution syndrome many clinicians advocate delaying HAART until the acute symptoms of disease resolve with CMV therapy. Conversely, some clinicians argue that starting HAART alone in patients with mild to moderate CMV GI disease is a safe and reasonable first step rather than initially starting with directed CMV therapy. However, the available data does not favor one therapeutic strategy over the other.

## ADENOVIRUS

Gastrointestinal adenovirus excretion occurs at an advanced stage of HIV disease and is associated with a poor prognosis.<sup>64–68</sup> It is seen when CD4+ lymphocyte count is less than 200/ $\mu$ L. Adenovirus has been linked to “pathogen-negative” persistent diarrhea in patients with a characteristic colitis. Adenovirus infected cells show characteristic amphophilic or eosinophilic nuclear inclusions, predominantly affecting the surface epithelium and characteristically involving the goblet cells.

## HERPES SIMPLEX AND VARICELLA ZOSTER VIRUSES

Herpes simplex is frequently associated with proctitis or distal colitis and may result in mild diarrheal illness or even constipation.<sup>63–68</sup> Small vesicles are seen on the colonic mucosa that rupture to form small rounded ulcers and may coalesce to form a large ulcer. Histologically typical inclusion bodies are seen (Fig. 77.7a,b). Gastrointestinal complications of herpes zoster are very rare, with most cases showing only temporal or

**Fig. 77.7a:** Photomicrograph of colonic biopsy showing crypt epithelial lining with enlarged nuclei, many of the nuclei show intranuclear reddish irregular inclusions (H&E,  $\times 450$ ).

**Fig. 77.7b:** Photomicrograph of the same biopsy showing a positive staining of many intranuclear inclusions stained brown color in immunostained section (PAP,  $\times 450$ ).

radiological evidence. It can also present as pseudo-obstruction and toxic megacolon.

## FUNGAL INFECTIONS

The most common organism is *Histoplasma capsulatum* especially disseminated, with 75% having gastrointestinal involvement.<sup>36</sup> *Candida* colitis is generally asymptomatic but it may occasionally produce discrete ulcers resembling viral disease.<sup>36,62</sup>

## BACTERIAL INFECTIONS

Salmonella (*S. typhimurium*, *S. enteritidis*), Shigella (*S. flexneri*, *S. dysenteriae*, *S. sonnei*), and *Campylobacter jejuni* have a high incidence of diarrheal disease among the immunocompromised and represent significant pathogens in HIV disease.<sup>36</sup> *Mycobacterium avium* complex (MAC) infection is seen when CD4+ counts decline to less than 50 cells/ $\mu$ L. Diarrheal illness is typically protracted and associated with abdominal pain, anorexia, fever, weight loss, anemia, and night sweats.<sup>36,44</sup> Complications include obstruction, fistula formation, bleeding, and perforation.<sup>59</sup> Endoscopically, MAC infection appears as granular white nodules 2–4 mm in diameter with surrounding erythema.

Initial, first-line treatment for MAC consists of two antibiotics: clarithromycin and ethambutol. Each agent alone has high rates of drug resistance, whereas a combination of the two results in complete microbiologic response, lower relapse rates, improved clinical symptoms, and overall better survival. Rifabutin is another antibiotic effective against MAC and can be added to the regimen to counter problem of resistance and some resultant increased efficacy. Some guidelines have recommended addition of either injectable amikacin or streptomycin to therapy for patients at high risk of death from MAC, which include patients with CD4 T-cell counts of 50 cells/ $\mu$ L or less, high mycobacterial load, or in the absence of HAART. MAC treatment is lifelong or until immune function has improved with HAART.

Human intestinal spirochetosis is a condition defined by the presence of a layer of spirochetes attached by one end to the colorectal epithelium. The pathologic significance is uncertain, but it has been associated with chronic diarrhea and abdominal complaints in HIV-positive patients.<sup>69</sup> Two anaerobic species, *Brachyspira pilosicoli* and *Brachyspira aalborgi*, are commonly implicated.<sup>69</sup>

*Clostridium difficile* has been implicated as the causative organism in 10–25% of patients who have antibiotic-associated diarrhea, in 50–75% of those who have antibiotic-associated colitis, and in 90–100% of those who have antibiotic-associated pseudomembranous colitis.<sup>70–72</sup> In those who acquire *Clostridium difficile*, the immune status of the host is an important determinant of the outcome. Patients who have more severe underlying illnesses are more likely to develop symptomatic disease. The clinical presentation of *Clostridium difficile* colitis is variable. Some individuals who even have toxigenic strains in stool remain asymptomatic. Patients who have symptoms can have disease that can range from diarrhea, colitis without pseudomembranes, pseudomembranous colitis, to fulminant colitis. Some patients have disease primarily in the cecum and right colon, presenting with marked leukocytosis and abdominal pain but little or no diarrhea. Colonoscopic features for pseudomembranous colitis are pathognomonic for this disease. On endoscopy, the colonic mucosa is studded with adherent raised yellowish plaques that can easily be dislodged (Fig. 77.8). Pseudomembranes tend to be most pronounced in the rectosigmoid area. The main prerequisite

**Fig. 77.8:** Colonoscopic view—exudative lesions of *C. difficile* colitis.

for *Clostridium difficile*-associated disease is antibiotic usage. Other risk factors that have been described include: degree of severity of underlying illness, use of proton pump inhibitors, gastrointestinal surgery, older patient age, prolonged hospital stay, stay in the ICU, and tube feeding.<sup>70–72</sup>

The cell cytotoxicity assay has been regarded as the “gold standard” for the diagnosis of *Clostridium difficile* infection. It is a labor-intensive process, and results take up to 48–72 hours. Various EIAs are commercially available that use monoclonal antibodies to toxin A, toxins A and B together, or the other common antigen (glutamate dehydrogenase). These tests are easy to use, and are much less costly. Polymerase chain reaction amplification of toxin B gene for diagnosis of *Clostridium difficile* infection is also commercially available. Recommendations for treating *Clostridium difficile* colitis include discontinuation of antibiotics, supportive nonspecific therapy, and addition of metronidazole for those who fail to respond within 2–3 days. Oral vancomycin was recommended for patients (i) who were critically ill, unable to tolerate metronidazole, pregnant, or younger than 10 years; (ii) who failed initial therapy with metronidazole; or (iii) whose organism proved to be metronidazole resistant. Doses of vancomycin ranging from 125 to 500 mg 4 times daily were found to be equally effective. A randomized trial comparing metronidazole and vancomycin in 92 patients for 10 days noted similar rates of response (88% for vancomycin and 90% for metronidazole) and recurrence (12% for vancomycin and 5% for metronidazole) within a 21-day follow-up period.<sup>70–72</sup> Other agents which have been used successfully in the treatment of this condition include bacitracin, teicoplanin, fusidic acid, nitazoxanide, rifaximin, and probiotics.

## HIV Enteropathy

HIV may be transported through the M cells directly to the mucosal lymphoid follicles. Alternatively, it may infect enterocytes via Fc receptor (by antibody bound HIV) or via CD4 independent receptor (by successive budding on the basal side) to reach the lamina propria. In addition, these changes may be responsible for the partial small intestinal mucosal atrophy and maturational defects seen in these patients. In 20% HIV-positive patients with diarrheal illness, no cause is found. These cases are labeled as HIV enteropathy or HIV colitis.<sup>73–79</sup> The HIV is seen in the mononuclear cells of lamina propria in 30–39% of patients with AIDS. Depletion and functional impairment of the mucosal CD4+ cells with altered cytokine secretion may explain the breakdown of mucosal barrier leading to secondary opportunistic or nonopportunistic infections and secondary malignancies.<sup>73–79</sup>

## EVALUATION OF A PATIENT WITH DIARRHEAL ILLNESS (TABLE 77.3)

Routine stool testing is reasonable depending on the suspected cause and duration (acute vs. chronic) of symptoms and has a yield of 13–75% depending on the epidemiological setting, CD4 count, and number of stool tests performed.<sup>30,34,37–39</sup> In

**Table 77.3:** Diagnostic Work Up for Evaluation of Diarrhea in HIV-positive Patients

- Bacterial culture (to detect *Salmonella* species, *Shigella* species, etc.)
- Ova and parasite examination
- *C. difficile* toxin assay
- Modified acid-fast stain or immunofluorescence kit (cryptosporidia)
- Modified trichrome stain (microsporidia)
- Blood culture in febrile patients
- Flexible sigmoidoscopy/colonoscopy with mucosal biopsies from abnormal looking area
  - Light microscopy (mycobacteria, CMV, cryptosporidia, etc.)
  - Mycobacterial culture
  - PCR for tuberculosis and other agents
- Upper endoscopy and biopsies from abnormal looking areas
  - Light microscopy (giardia, strongyloides, CMV, mycobacteria, cryptosporidia)
  - Mycobacterial culture
  - PCR sample for various agents

many cases, no infectious agent can be identified as the cause of gastrointestinal abnormality. Specific diagnosis depends on stool studies and invasive methods like endoscopic examination of gastrointestinal tract. Analysis of duodenal/bile juice is a simple, rapid, and effective method, which increases the yield of detection of enteral pathogens. Special histological stains for fungal, mycobacterial, and viral infections do not increase the diagnostic yield but add to the cost.<sup>63</sup> For patients with CD4+ cell counts less than 100/ $\mu$ L and AIDS-related unexplained diarrhea, flexible sigmoidoscopy with biopsy is desirable.

Prospective studies have shown a high yield of endoscopic examination with biopsy of the lower and upper GI tract in patients with negative stool tests, with a diagnosis established in 65–82%.<sup>30,34,37–39</sup> For those with complaints referable to the distal colon (bright red rectal bleeding, tenesmus, urgency), examination of the distal bowel will often establish the diagnosis, with CMV being the most common cause found. However, one study suggested that CMV colitis may be limited to the right colon in a third of patients, supporting the use of full colonoscopy if the distal colon is endoscopically normal.<sup>30–33,37,38</sup>

## TREATMENT OF DIARRHEAL DISEASE

Recommended regimens for diarrheal diseases in AIDS are given in Table 77.4.<sup>30</sup> Since the introduction of HAART, the prevalence of HIV-related opportunistic infections has significantly decreased in developed countries.<sup>30,34–37</sup> Diarrheal diseases due to opportunistic pathogens are less common than before. Control of HIV replication and immunodeficiency by HAART offers new therapeutic options in cryptosporidiosis and microsporidiosis.

## General or Nonspecific Measures in HIV-Infected Patients with Diarrhea

### Highly Active Antiretroviral Therapy (HAART)

HAART can reduce the patients' load of HIV to a great extent, many times even to an undetectable range.<sup>30,33–40</sup> This may stop further destruction of CD4 lymphocytes and results in

improvement in the degree of immunosuppression. The course of diarrheal disease may be dramatically altered in many, but not all, patients who are compliant with treatment. The benefits of HAART on treating gastrointestinal opportunistic infections are unquestionable and it should be part of the therapy of most gastrointestinal opportunistic infections. However, timing of starting HAART needs to be decided judiciously. Electrolyte imbalance, dehydration, and malnutrition should be corrected, at least to some extent, before starting HAART. Some of the antiretroviral agents, in particular the protease inhibitors such as nelfinavir, fosamprenavir, and ritonavir, are well-known to cause diarrhea. Initiation of HAART may result in immune reconstitution syndrome, and some patients may have temporary worsening of their gastrointestinal or diarrheal symptoms

### Antimotility Agents

Antimotility agents (loperamide, diphenoxylate, codeine) decrease stool output by decreasing GI motility and increase transit time, thus generally promoting fluid and electrolyte absorption. They are somewhat helpful in alleviating the symptoms of mild to moderate diarrhea.

### Adsorbent Drugs

Adsorbents like bismuth subsalicylate and kaolin/pectin are widely used and may be somewhat helpful in treating mild to moderate diarrhea, particularly in pathogen negative group.

### Octreotide

Many clinical studies have evaluated octreotide in patients with AIDS-related diarrhea. The overall clinical response rates to subcutaneous octreotide range from 25% to 40% in most studies. The usual dose is 100–300  $\mu$ g given subcutaneously 3 times a day. Response rate may be better in pathogen negative cases of diarrhea.

## Liver Diseases

Liver disease in patients with HIV and AIDS presents with varied symptoms including fever, right upper quadrant pain, and hepatomegaly. Almost 90% of patients have abnormalities of the liver enzymes at presentation, while 60–73% have enlarged liver.<sup>80–86</sup> Various causes of liver diseases in HIV/AIDS patients are listed in Table 77.5.

## HEPATITIS C VIRUS AND HIV/AIDS

HIV-induced immunosuppression may increase replication of HCV, leading to higher HCV RNA levels and accelerated progression to chronic HCV infection.<sup>80–87</sup> An individual may become infected with multiple strains of HCV and more virulent subtypes may predominate. HCV infection induces CD4+ stimulation, which may increase HIV replication, although it does not increase the severity of HIV infection. There is widespread expression of inducible nitric oxide (NO) synthase in the hepatocytes in chronic HCV liver disease, irrespective of

**Table 77.4:** Preferred Treatment of Specific Pathogens Causing Diarrhea in Subjects Infected with HIV<sup>30</sup>

Pathogen	Preferred therapy
Cryptosporidia	Combination antiretroviral therapy along with any of the following <ul style="list-style-type: none"> <li>Nitazoxanide 500–1000 mg PO bid for 2 weeks</li> <li>Paromomycin 25–35 mg/kg PO daily for 2 weeks</li> <li>Paromomycin 1 g PO bid/Azithromycin 600 mg PO daily for 4 weeks</li> </ul>
<i>Cyclospora cayentanensis</i>	Trimethoprim/sulfamethoxazole 160/800 mg PO qid for 1 week Alternatives – any of the following <ul style="list-style-type: none"> <li>Ciprofloxacin 500 mg PO bid for 1 week</li> <li>Nitazoxanide 500 mg PO bid for 3 days</li> </ul>
<i>Isoospora belli</i>	Trimethoprim/sulfamethoxazole 160/800 mg PO qid for 10 days Alternatives – any of the following <ul style="list-style-type: none"> <li>Ciprofloxacin 500 mg PO bid for 7 days</li> <li>Nitazoxanide 500 mg PO bid for 3 days</li> <li>Pyrimethamine 50–75 mg PO daily for 3–4 weeks</li> </ul>
Microsporidia <i>Encephalitozoon intestinalis</i>	Combination antiretroviral therapy and Albendazole 400 mg PO bid for 2 weeks
Microsporidia <i>Enterocytozoon bienersi</i>	Combination antiretroviral therapy Fumagillin 60 mg PO daily for 2 weeks
Cryptococcus	Initial phase: Amphotericin B deoxycholate 0.7 mg/kg IV daily (or liposomal amphotericin B 4–6 mg/kg IV daily) and Flucytosine 25 mg/kg PO qid for 2 weeks Continuation phase: Fluconazole 400 mg PO daily for 8 weeks
Cytomegalovirus	Combination antiretroviral therapy with any of the following <ul style="list-style-type: none"> <li>Ganciclovir 5 mg/kg IV bid for 3–6 weeks</li> <li>Foscarnet 90 mg/kg IV bid for 3–6 weeks</li> <li>Valganciclovir 900 mg PO bid for 3–4 weeks</li> </ul>
MAC	Clarithromycin 500 mg PO bid Ethambutol 15 mg/kg PO daily (with or without Rifabutin 300 mg PO daily) for 12 weeks
<i>Mycobacterium tuberculosis</i>	Initial phase: All of the following for 2 months <ul style="list-style-type: none"> <li>Isoniazid 5 mg/kg PO daily</li> <li>Rifampicin 10 mg/kg PO</li> <li>Pyrazinamide 15–30 mg/kg PO daily</li> <li>Ethambutol 15–25 mg/kg PO daily</li> </ul> Continuation phase: All of the following for 6 months <ul style="list-style-type: none"> <li>Isoniazid 5 mg/kg PO daily</li> <li>Rifampicin 10 mg/kg PO</li> </ul> See NIH/CDC/HIVMA/IDSA/RNTCP guidelines for details
<i>Campylobacter jejuni</i>	Ciprofloxacin 500 mg PO bid for 1–2 weeks OR Azithromycin 500 mg PO daily for 1–2 weeks
Salmonella	Ciprofloxacin 500–750 mg PO bid for 1–6 weeks OR Trimethoprim/sulfamethoxazole 160/800 mg PO bid for 1–6 weeks
Shigella	Ciprofloxacin 500 mg PO bid for 1–2 weeks OR Trimethoprim/sulfamethoxazole 160/800 mg PO bid for 1 week or Azithromycin 500 mg PO on day 1, then 250 mg PO daily for 4 days

stage of liver disease. However, elevated NO levels in the serum are related only to active AIDS related bacterial, protozoal, and fungal infections, rather than to chronic viral infection with HCV or HIV alone. It may play a role in the local control of chronic viral infection at the tissue level. The responsiveness of these patients to drugs is also reduced. Antiretrovirals may slow the progression of HIV and modulate the presumed HIV/HCV interaction. The response to interferon is seen in only 25% of the patients. The immune improvement seen with protease inhibitor regimens helps reduce HCV load.

HCV, HIV, and hepatitis B virus (HBV) share similar routes of parenteral transmission, which include exposures to infected blood or blood products, sexual transmission among heterosexuals and men who have sex with men, and vertical transmission from an infected mother to her neonate during childbirth. The prevalence of chronic hepatitis C infection in patients with HIV has been reported to be in the range of 25–30%.<sup>80–87</sup> The prevalence, however, is substantially higher in HIV-infected injection drug users, and may be more than 85% but coinfection among persons with sexual transmission as the only risk factor

is less than 10%. The available data suggests that majority of the coinfecting individuals acquire HIV after having been already infected with HCV. However, it is important to note that a person infected with HIV who later becomes infected with HCV is much less likely to clear the acute HCV infection spontaneously. Whereas 14–45% of patients with acute HCV mono-infections immunologically clear HCV within 6 months, only about 5% of patients with HIV infection spontaneously clear an acute HCV infection, and those with lower CD4 cell counts do so even less frequently. In addition, liver disease appears to progress more quickly to advanced fibrosis and cirrhosis in patients with HCV-HIV coinfection. Approximately 6% of HIV-positive persons fail to develop HCV antibodies; therefore, HCV RNA should be assessed in HIV-positive persons with unexplained liver disease who are anti-HCV negative. However, there is no validated evidence that HCV co-infection significantly alters the natural history of HIV infection.

It is now clear that HIV infection has a detrimental impact on the natural history of HCV infection. Prior to the use of HAART, patients infected with HIV succumbed to AIDS-related complications rather rapidly. With the advent of HAART, however, HIV infections became controllable. As HIV-infected patients lived longer, mortality related to the progression of HCV-related advanced liver disease and its complications of liver failure, variceal

**Table 77.6:** Testing and Treatment of HCV Infection in the Setting of HIV (American Association for Study of Liver Diseases, 2009)<sup>87</sup>

- Anti-HCV testing should be performed in all HIV-infected.
- HCV RNA testing should be performed to confirm HCV infection in HIV-infected persons who are positive for anti-HCV, as well as in those who are negative and have evidence of unexplained liver disease.
- Hepatitis C should be treated in the HIV/HCV coinfecting patient in whom the likelihood of serious liver disease and a treatment response are judged to outweigh the risk of morbidity from the adverse effects of therapy.
- Initial treatment of hepatitis C in most HIV-infected patients should be peginterferon alpha plus ribavirin for 48 weeks at doses recommended for HCV mono-infected patients.
- When possible, patients receiving zidovudine (AZT) and especially didanosine (ddI) should be switched to an equivalent antiretroviral agent before beginning therapy with ribavirin.
- HIV-infected patients with decompensated liver disease (CTP score >7) should not be treated with peginterferon alpha and ribavirin and may be candidates for liver transplantation.

hemorrhage, and hepatocellular carcinoma became major causes of mortality in HCV-HIV coinfecting patients. Although an inverse relationship has been suggested between the CD4 count and hepatic fibrosis in patients with HCV-HIV coinfections, significant fibrotic progression also can occur in coinfecting patients with relatively high CD4 cell counts.<sup>82–87</sup>

Over the years, the treatment of HCV infection has evolved and the current standard therapy includes a combination of pegylated interferon and ribavirin for 24–48 weeks depending on genotype (Table 77.6).<sup>87</sup> The safety, efficacy, and tolerability of pegylated interferon and ribavirin for the treatment of HCV in HCV-HIV coinfecting patients was assessed in many published studies. Overall, the rates of sustained virological response (SVR) were lower than those observed in patients with HCV infection alone, which was in part due to excessive rates of discontinuation because of adverse events and poor tolerability of the antiretroviral drugs. Rate of SVR for genotype 1 and 4 varies from 14% to 38%, and for genotype 2 and 3 it varies from 44% to 73%.<sup>87</sup> But rate of discontinuation of drugs, mostly due to drug related adverse effects, varies from 12% to 39%. However, combination of pegylated interferon and ribavirin can not be used in all stages of HCV infection, it needs to be avoided in those with decompensated cirrhosis, advanced cirrhosis with a high risk of decompensation, significant cytopenias, active infections, immune mediated diseases, and autoimmune diseases. A Child-Turncote-Pugh (CTP) score of 7 or more or model for end-stage liver disease (MELD) score of 15 or more also portend an unacceptable rate of complications.

There is well-described hepatotoxicity associated with HAART but the current evidence suggests that HAART therapy appears to be of benefit from both the HIV and liver disease point of view, and should be considered in all coinfecting patients.<sup>80–85</sup> The results from several recent studies have indicated that liver-related outcome in coinfecting patients receiving HAART are superior to those in coinfecting patients not receiving HAART.

## HEPATITIS B VIRUS AND HIV/AIDS

Coinfection with HBV and HIV-1 is common because of the shared mode of transmission. Data indicate a wide range of coinfection prevalence (7–70%) in patients who are infected with HIV.<sup>80–86,88–93</sup> Immunologic dysfunction induced by HIV is expected to modify the course of HBV infection as 20% of HIV-infected patients become chronically infected against only 5% in the general population. The ability to clear HBsAg is dependent upon the CD4+ cell count.<sup>88–100</sup> The natural history of HIV and HBV has been altered with the advent of HAART.<sup>80–86,91</sup> There is evidence to suggest that the reconstituted immune system itself can cause an initial flare of transaminase levels, as a result of the onset of a strong cytotoxic T-lymphocyte response. Lamivudine, often administered as a component of HAART for HIV, is highly inhibitory to HBV and can lead to reductions in HBV DNA and HBeAg and normalization of aminotransferase levels in HBV-infected patients.<sup>80–86,91</sup>

Lamivudine, emtricitabine, and tenofovir are highly active against both HIV and HBV. However, the rate of HBV resistance to lamivudine in HBV/HIV coinfecting patients is high, reaching 90% in 4 years. Tenofovir plus lamivudine or emtricitabine are commonly prescribed as components of HAART in HBV/HIV coinfecting patients. Tenofovir is effective against lamivudine-resistant HBV. Adefovir in the approved dose for HBV (10 mg) has negligible activity against HIV. Entecavir has also been shown to decrease serum HIV RNA levels in lamivudine-experienced as well as in lamivudine-naïve patients. Clinical studies in patients with HBV/HIV coinfection reported lower response rates to IFN- $\alpha$  treatment than those with HBV monoinfection. Responders tend to have a higher mean CD4 cell count than nonresponders.

**Table 77.7:** Recommendations for Treatment of Patients with HBV/HIV Coinfection (American Association for Study of Liver Diseases, 2009)<sup>91</sup>

### Indications of therapy

- Patients who meet criteria for chronic hepatitis B should be treated.
- Liver biopsy should be considered in patients with fluctuating or mildly elevated ALT (1–2 times of normal)

### Choice of therapy

- Patients who are not on HAART and are not anticipated to require HAART in the near future should be treated with an antiviral therapy that does not target HIV, such as pegylated interferon or adefovir.
- Patients in whom treatment for both HBV and HIV is planned should receive therapies that are effective against both viruses: lamivudine plus tenofovir or emtricitabine plus tenofovir are preferred.
- Patients who are already on effective HAART that does not include a drug active against HBV may be treated with pegylated interferon or adefovir.
- In patients with lamivudine resistance, tenofovir should be added.
- When HAART regimens are altered, drugs that are effective against HBV should not be discontinued without substituting with another drug that has activity against HBV, unless the patient has achieved HBeAg seroconversion.

Standard criteria for treatment are applicable for the treatment of HBV infection in the setting of HIV (Table 77.7).<sup>80–86,91</sup> Given that antiretroviral regimens may include drugs with activity against HBV, it is reasonable to base HBV treatment decisions on whether or not HIV treatment is ongoing or planned. In HBeAg-positive patients who are not in need of HAART, or who are already well-controlled on HAART that does not include a drug with activity against HBV, pegylated interferon may be considered as a first-line option given its limited duration, but adefovir can also be used in this setting.<sup>80–86,91</sup> It is generally recommended that candidates for interferon therapy should have CD4 cell counts >500 cells/mL. Patients who have lower CD4 cell counts or who are HBeAg-negative may be appropriate candidates for adefovir. Finally, in HBeAg-negative patients who are likely to need HIV treatment in the future, earlier initiation of HAART may be considered. For patients in whom HAART initiation is planned, it is best to use a regimen that includes drug/drugs with activity against HBV. Most experts recommend using two drugs.<sup>80–86,91</sup> Combinations can include tenofovir plus lamivudine or tenofovir plus emtricitabine. When HAART regimens are altered, drugs that are effective against HBV should not be discontinued without substituting another drug that has activity against HBV, unless the patient has achieved HBeAg seroconversion and has completed an adequate course of consolidation treatment.

The treatment of HBV in patients with AIDS is disappointing due to the immunosuppression and comorbidity. Patients have higher levels of HBV DNA, lower pretreatment transaminase levels and less hepatic inflammation, all indicators of poor response to interferon.<sup>91–103</sup> The response rate is only 8.3% at the end of 3 months. The response rate to vaccination is also disappointing with a nonresponse in 40% as compared to 2.5–5% in immunocompetent individuals. Up to 70% of IV drug abusers have hepatitis delta virus infection, which is associated with a serious outcome. These patients have highly elevated transaminases and are more prone for reactivation and development of fulminant disease.

## OTHER VIRAL INFECTIONS

CMV hepatitis is usually subclinical and characterized by mild transaminitis and mild cholestasis. It is typically associated with sparse hepatonecrosis, periportal, and perivenous infiltrate, and cells with large intranuclear and small cytoplasmic inclusions.<sup>104</sup> It can also cause mass lesions simulating neoplasia or granulomatous infiltration. Herpes simplex virus causes severe aminotransferase elevations. On histology, it shows Cowdry type A intranuclear inclusions.<sup>104</sup> HIV infects the Kupffer cells and sinusoids, which represent a potential barrier to infection of the underlying hepatocytes. Studies have shown that it can cause limited cytolysis and alteration of the phagocytic and synthetic function.

## GRANULOMATOUS INFLAMMATION

It is characterized by elevated levels of alkaline phosphatase as a result of infiltration of hepatic parenchyma and obstruction of the terminal branches regardless of the cause. The common causes include mycobacterial, fungal, and protozoal infections.<sup>105</sup>

Both pyogenic and amoebic liver abscesses can complicate the course of HIV-seropositive individuals (Fig. 77.9a,b).

## FATTY LIVER (STEATOSIS) IN AIDS

Steatosis in HIV-seropositive patients may result from HIV itself, the use of nucleoside analogs (some of which have been implicated in acute liver cell failure), and concurrent infections with hepatitis B and C.<sup>80–86,106</sup> In addition, the other common causes like alcohol and diabetes also need to be considered in this subset of individuals.

## KAPOSI SARCOMA

It is the most common hepatic neoplasm seen in patients with AIDS, usually there is associated cutaneous involvement.<sup>30–34,103–105</sup>

**Fig. 77.9a:** Ultrasound scan showing multiple pyogenic abscesses in the liver. *Courtesy: Dr. Suman Kochhar, Professor of Radiodiagnosis, GMCH, Chandigarh.*

**Fig. 77.9b:** Contrast enhanced CT scan of abdomen showing multiple abscesses in the liver. *Courtesy: Dr. Suman Kochhar, Professor of Radiodiagnosis, GMCH, Chandigarh.*

It tends to originate in the capsular, hilar, and portal areas and invades the parenchyma from these sites. Non-Hodgkin lymphoma also has a high incidence of involvement of the liver.

## HEPATOTOXIC DRUGS

Hepatotoxicity as a complication of HAART is too well-known as significant hepatotoxicity occurs in about 6% to 10% of patients.<sup>80–85,105–107</sup> The severity of the hepatotoxicities ranges from asymptomatic elevations of aminotransferase levels to fatal acute liver failure. Life-threatening events related to hepatic damage occur in about 2.6 per 100 person-years on ART. HCV infection, HBV infection, and alcohol abuse have been identified as risk factors for hepatotoxicity caused by HAART. The possible mechanisms of hepatotoxicity of HAART include direct toxicity from individual component drugs, mitochondrial toxicity of nucleoside agents, idiosyncratic hypersensitivity reactions, induction of hepatic metabolic abnormalities, and immune-mediated following reconstitution of immune activity in patients coinfecting with HIV and HCV or HBV.<sup>82–84</sup>

Nucleoside reverse transcriptase inhibitors (NRTIs) are known to have a potential for mitochondrial toxicity.<sup>82–84</sup> Pharmacologically designed to be incorporated into viral nucleic acids and to act as chain terminators, these drugs also inhibit human mitochondrial DNA polymerase  $\gamma$  (an enzyme necessary for mitochondrial DNA replication), leading to reduced mitochondrial DNA content and altered mitochondrial morphology. Toxicity typically occurs more than 6 months after initiation of therapy and manifests with lactate acidosis and elevations in serum lactic dehydrogenase, amylase, or lipase levels, as well as liver chemistry tests. In contrast, the non-nucleoside reverse transcriptase inhibitors tend to cause immune-mediated adverse drug reactions, with nevirapine-based regimens being the most frequently involved. Most reactions occur during the initial 4 weeks of therapy. In addition to elevated liver chemistry tests, clinical features of hypersensitivity such as leukocytosis, elevated immunoglobulin-E levels, and eosinophilia are typically present.

Significant hepatotoxicity is seen in about 10% of patients treated with protease inhibitors class of drugs, with ritonavir having the highest risk.<sup>82–84</sup> The incidence of toxicity tends to increase over time with duration of drug exposure. Ribavirin has significant drug interaction with many agents which are part of HAART. Ribavirin should never be used in combination with didanosine as this combination is known to lead to potentially fatal mitochondrial toxicity with lactic acidosis. Zidovudine and ribavirin should also be avoided as this combination is known to be associated with substantially greater anemia or neutropenia than observed with either agent alone.

## Patterns of Hepatotoxicity in HIV-Infected Patients on Drug Therapy (Table 77.8)

### Hepatitis and Increased Transaminase Levels

Hepatic injury is often defined as increases in aspartate aminotransferase (AST)/alanine aminotransferase (ALT) levels

**Table 77.8:** Commonly Used Hepatotoxic Drugs in HIV-Infected Patients

Hepatocellular	Cholestatic	Mixed
Zidovudine	Albendazole	Co-trimoxazole
Dideoxyinosine	Macrolides	Carbamazepine
Ketoconazole		Ganciclovir
Antitubercular drugs		
Antiepileptics		
Ganciclovir		
Pentamidine		
Nevirapine		

that are 3–5 times more than the upper limits of normal or the patient's baseline values before initiation of ART.<sup>82–84</sup> About 5–10% of patients have increased liver enzyme levels after the initiation of ART. All drug classes of ART have the potential to cause severe liver injury progressing to fulminant hepatic failure. Although the injury may be caused by ART, the differential diagnosis of such increases is vast, including acute or chronic viral hepatitis (hepatitis A, B, C or D, cytomegalovirus, Epstein–Barr virus), ethanol or substance abuse, systemic or opportunistic infections, nonalcoholic steatosis, and malignancies. Patients infected with HIV with clinical signs of hepatitis, such as fatigue, nausea, vomiting, and right upper quadrant abdominal pain and tenderness need further evaluation, and consideration must be given to stopping one or more of the drugs from the ART drug regimen. Patients with asymptomatic rise of transaminases may possibly be observed closely and followed up.

#### **Isolated Rise in Bilirubin without Raised Transaminases**

About 40% of individuals receiving atazanavir develop a significant increase in their total bilirubin level, 5% of patients develop jaundice, although none of them develop clinically significant hepatotoxicity.<sup>82–84</sup> This increase in total bilirubin level may be caused by a similar mechanism as Gilbert syndrome involving inhibition of UGT1A1 (UDP glucuronosyltransferase), an enzyme required for conjugation of bilirubin. Indinavir causes unconjugated hyperbilirubinemia in 10% of the patients; isolated rise in serum bilirubin may not require discontinuation of the drug.

#### **Hypersensitivity Syndrome**

Hypersensitivity syndrome is a life-threatening syndrome that is caused by an immune reaction to either the parent drug or a metabolite and is best described with abacavir.<sup>82–84</sup> The immune-mediated response can affect the liver as well as other organs, such as the skin, lungs, kidney, and heart. It most often occurs within the first few days of initiating therapy, but may occur as late as 8 weeks. The most common symptoms are fever, rash, nausea, and vomiting. 80% of patients have fever, and 70% have rash.

Patients may also exhibit myalgias, headache, diarrhea, pruritus, lymphadenopathy, mucocutaneous involvement, hypotension, and respiratory symptoms such as cough, dyspnea, or pharyngitis. In addition to raised transaminases, the patients can have leukopenia, thrombocytopenia, and raised creatinine levels. It is critical to have a high suspicion for the presence of this syndrome, as it may progress rapidly to multisystem organ failure. Early stoppage of the offending drug is the mainstay of the treatment and the clinical improvement may start within days of discontinuation of the offending drug.

#### **Hepatic Steatosis**

Mitochondrial damage is believed to be a prominent cause of hepatic steatosis. The NRTIs can reduce the replication of mitochondrial DNA (mtDNA) in a manner similar to their effects on the HIV DNA replication. Hepatic steatosis remains mostly asymptomatic but may be associated with symptoms suggestive of hepatitis in some patients.<sup>82–84,105,106</sup>

#### **Lactic Acidosis**

One of the most severe complications recognized as a risk of ART is the development of symptomatic hyperlactatemia with metabolic acidosis. The mitochondrial toxicity responsible for causing hepatic steatosis may also cause this disorder, which seems to be exclusive to NRTIs.<sup>82–84</sup> Disruption of oxidative phosphorylation prevents aerobic energy production and reduces lactate clearance. A patient is considered to have lactic acidosis if his pH is less than 7.3 and bicarbonate less than 20 mEq/L with any abnormal increase in serum lactate level. Lactic acidosis may develop within months to years after the initiation of ART (specifically an NRTI). Factors that increase the risk for this adverse event include NRTI use for greater than 6 months, pregnancy, female sex, age greater than 40 years, lower CD4 count, concurrent use of stavudine and didanosine, use of hydroxyurea or ribavirin with didanosine, obesity, and an increased body mass index. Patients with lactic acidosis mostly present with nonspecific signs and symptoms but severe cases may be associated with severe hepatocellular dysfunction, encephalopathy, ascites, cardiovascular instability, and multi-organ dysfunction. Patients with moderate to severe increases in serum lactate level, with an acidosis, or who are symptomatic should have their NRTI discontinued immediately. In severe cases, sodium bicarbonate therapy and hemodialysis with bicarbonate buffer have been used. Because of the proposed mechanism of mitochondrial dysfunction, several cofactors have also been used with varying success, including thiamine, riboflavin, L-carnitine, and coenzyme Q.

These represent one of the most common causes of abnormal liver enzymes, with almost 90% being treated with a hepatotoxic medication necessitating dosage reduction. Widespread use of co-trimoxazole for prophylaxis makes it the most common cause of drug-related hepatotoxicity in HIV/AIDS.

## Gallbladder and Biliary Tract Diseases

Signs of biliary tract disease in HIV-infected patients (pain, fever, and jaundice) do not differ from noninfected patients except that jaundice is less common. Besides AIDS related cholangitis, HIV-infected patients may develop biliary disease unrelated to HIV, the clinical pattern being similar regardless of the organism involved. Clinical features include right upper abdominal pain (90%), significant weight loss (75%), diarrhea (66%), jaundice (10%), and uncommonly pruritus.<sup>108–119</sup>

Most patients develop cholangitis years after the initial diagnosis of HIV in advanced disease.<sup>108–112</sup> AIDS cholangitis can be an AIDS defining diagnosis. Anicteric cholangitis is a predominant finding with mean alkaline phosphatase level of 750 U/dL. Serum bilirubin exceeding 2 mg/dL occurs in only 15% patients and transaminase elevation is less than twice the normal. CD4+ count is always less than 100 cells/ $\mu$ L. The pathogenesis is not known, one theory suggests a stereotypic type of injury regardless of the nature of underlying disease. Often the causes include immunologic attack, enteric infection, and ischemic injury. The organisms identified are cryptosporidium in 20–62% patients, cytomegalovirus in 23–42%, both the organisms in 23%, and microsporidia (enterocytozoon), *Mycobacterium avium intracellulare*, and *Giardia lamblia* in less than 10%.<sup>111–119</sup>

The diagnosis is based on the typical cholangiographic findings in patients with advanced HIV disease, supported by demonstration of the pathogen in the blood, stool, bile, or biopsy specimen. The organisms can be detected in up to 75% of cases.<sup>108–112</sup> Imaging modalities are the next line of investigations. Abdominal ultrasound is abnormal in 75% of cases with dilatation of common bile duct (CBD) in 65–70% and intrahepatic bile duct in 15–20% only. Overall, 20–40% have thickening of the wall of CBD and more than 50% patients have thickening of gallbladder wall, but cholelithiasis is rarely seen.<sup>111–119</sup> Computerized tomography (CT) may demonstrate intrahepatic ductal dilatation better than ultrasound.

Endoscopic retrograde cholangiopancreatography (ERCP) is the gold standard for diagnosing AIDS-related cholangitis with four distinct patterns observed.<sup>116–118</sup>

1. Papillary stenosis is seen in 15–20% of the patients with dilatation of CBD more than 8 mm and smooth distal tapering with contrast retained for over 30 minutes (Fig. 77.10).
2. Sclerosing cholangitis, characterized by focal stricture and dilatation of intra- and extrahepatic ducts, is seen in 20% of patients.
3. Combined papillary stenosis and sclerosing cholangitis is seen in 50% of the patients.
4. Long extrahepatic bile duct stricture is seen in 15% of the patients without the presence of intrahepatic strictures suggesting that another cause is present.

The common bile duct often has a beaded or scalloped appearance. The left intrahepatic biliary ductal system is often more severely affected than the right. Intraluminal polypoidal filling defects within the CBD and large intrahepatic duct occur in up to 25% of

**Fig. 77.10:** Magnetic resonance cholangiopancreatography (MRCP) showing irregular and dilated common bile duct with a stricture at lower end, classical of papillary stenosis.

cases.<sup>116–118</sup> In primary sclerosing cholangitis, the common bile duct is rarely dilated with string-like strictures and saccular deformity on cholangiogram and paucity of bile ductules on liver histology.

### THERAPY

Only a few patients will die directly from AIDS-related cholangitis. Therefore, palliation of pain should be the major goal. The response to medication is poor, though ursodeoxycholic acid reportedly improves cholestasis. As more than 70% of patients have papillary stenosis, sphincterotomy has been tried. This may result into the improvement of pain and decrease in CBD diameter, but more than one half of the patients continue to progress into intrahepatic disease. The prognosis of the condition is poor as AIDS cholangitis is a manifestation of late disease with a median survival of 7 months.<sup>112–118</sup>

### CHOLECYSTITIS

In AIDS, pain of cholecystitis is the most prominent feature, which is chronic and lasting for several months. In 66%, fever is prominent, in 50% weight loss, and in 25% vomiting is seen.<sup>118,119</sup> Laboratory data reveals a cholestatic picture. Transaminase and bilirubin levels are only mildly elevated and leukocytosis is not seen. It is a potentially serious condition requiring prompt recognition and gallbladder decompression.

Infection with cytomegalovirus, *Cryptosporidium* or both is common; rarely, *Cyclospora cayentanensis* is implicated.<sup>118–127</sup> The gallbladder wall is markedly edematous with thickness more than 1 cm. Stones are almost never found and bacterial superinfection is unusual. Patients generally have concomitant biliary disease.<sup>109</sup> Pain improves promptly following cholecystectomy. Mean survival is 7 months as acalculous cholecystitis is a late manifestation of the disease.

The presence of coexisting AIDS cholangiopathy in about half of the patients increases the likelihood of ongoing symptoms of

cholecystitis. Patients should be counseled that postoperative endoscopic retrograde cholangiopancreatography may be necessary and that some variants of AIDS cholangiopathy do not respond to endoscopic therapy.

## Pancreatic Disorders

Patients with HIV/AIDS are subject to the same diseases affecting the general population including alcoholic pancreatitis. In addition, certain other disorders peculiar to AIDS like opportunistic infections, neoplasms, and drug related side effects may occur.<sup>128–132</sup> Autopsy studies have found pancreatic lesions in 10% of patients with AIDS. Pancreatic lesions infrequently produce symptoms and are rarely recognized antemortem. Various causes and evaluation strategies for pancreatic dysfunction in AIDS are given in Table 77.9.

### ACUTE PANCREATITIS

Pancreatitis occurs in about 5% of adult patients and 17% of children with AIDS.<sup>128–137</sup> Clinical findings of pancreatitis are similar as seen in HIV-negative patients except that they are more likely to have pyrexia, diarrhea, hepatomegaly, leukopenia,

anemia, and hypoalbuminemia due to the immunosuppression and malnutrition. Unusual features of pancreatitis in AIDS include high frequency of drug induced pancreatitis (in almost 50% patients; most common offending drugs are pentamidine, dideoxyinosine, and co-trimoxazole) and low frequency of gallstone pancreatitis.<sup>128–130</sup> A significant proportion of patients with asymptomatic HIV infection have abnormally elevated serum trypsin and elastase levels, possibly only due to HIV infection. Development of pancreatitis is a poor prognostic sign in pediatric HIV patients. APACHE II scores are reasonably more sensitive and moderately robust predictors of severe disease than Ranson or modified Glasgow scale.

Although advanced HIV disease alone is associated with an increased incidence of pancreatitis, but NRTI use is independently linked to this complication. The incidence of pancreatitis in patients on didanosine (NRTI) ranges from 1% to 7%, with a 6% mortality.<sup>128–132</sup> This complication occurs most often 2–5 months after the initiation of ART. The concurrent use of didanosine with hydroxyurea increases the risk of acute pancreatitis by 4-fold. Other known risk factors are a CD4 count less than 200 cells/ $\mu$ L, age greater than 37 years, increased baseline amylase, and female gender.

The mechanism of pancreatic toxicity may be related to the mitochondrial toxicity of NRTIs. Protease inhibitors often induce hyperlipidemia, a known cause of acute pancreatitis. Approximately 50% of patients after 1 year on ART have newly diagnosed hyperlipidemia. There are several mechanisms believed to cause the dyslipidemia associated with ART, each mediated by alterations in different receptors and enzymes.

### AIDS CHOLANGIOPATHY

Pancreatogram in patients with papillary stenosis show that 81% have associated pancreatic duct dilatation, often with associated features of chronic pancreatitis.<sup>115–117</sup> It presents with a picture similar to that of sclerosing cholangitis. ERCP is the investigation of choice, which reveals localized stenosis, diverticula, saccular dilatation, and pruning of the intrahepatic ducts. It can also involve the juxta-ampullary region of the pancreas. Organisms implicated are CMV and cryptosporidia.<sup>115–117,136,137</sup>

### CHRONIC PANCREATITIS

The incidence of chronic pancreatitis in HIV-positive patients is 0.5%; the most common cause is alcohol.<sup>128–137</sup> Glucose intolerance is more likely to be due to drug toxicity, pentamidine, and dideoxyinosine being implicated. HIV itself has been known to cause beta cell dysfunction leading to type 1 diabetes.

### PANCREATIC ABSCESS

These patients are present with chronic fever, night sweats, rigors, malaise, and weight loss. Leukocytosis is not seen. Opportunistic infection with mycobacteria is among the common causes of pancreatic abscess. Kaposi sarcoma of the pancreas can mimic

**Table 77.9:** Evaluation and Differential Diagnosis of Pancreatic Dysfunction in HIV-infected Patients

<b>Hyperamylasemia without pancreatitis</b>
Due to renal failure—Heroin/AIDS nephropathy

<b>Pancreatic infection without pancreatic dysfunction</b>
Cytomegalovirus
<i>C. neoformans</i>
<i>M. avium intracellulare</i>

pancreatic cancer in HIV-infected patients. The diagnosis is made by demonstration of human herpes virus 8 (HHV-8) in the aspirated pancreatic juice/bile. There is good response to paclitaxel and antiretroviral therapy.<sup>138,139</sup>

### Non-AIDS-Related Pancreatic Disease

Alcoholic pancreatitis is more common among IV drug abusers who are more likely to have a worse prognosis, as they are severely malnourished and suffer from concomitant diseases. Gallstone pancreatitis is distinctly uncommon. Pancreatic adenocarcinoma is highly unusual but when it occurs it is more aggressive.

### Anorectal Disease (Table 77.10)

A highly risky form of unprotected anal intercourse 'bare backing' has emerged in male homosexuals posing new challenges in HIV prevention. The frequency of anorectal disease among homosexual AIDS patients is quite high.<sup>140–146</sup> Common findings in HIV-infected individuals include perirectal abscess, anal fistula, nonspecific ulcerations, and infectious proctitis; however, lymphoma and ulcerations caused by cytomegalovirus, tuberculosis, and histoplasmosis are also seen.<sup>140–143</sup> Gay bowel syndrome is characteristically seen in homosexuals practicing anoreceptive intercourse. Rectal use of nonoxynol-9 among men who have sex with men may increase the risk of transmission of HIV. There is a strong epidemiological correlation between sexually transmitted disease, anorectal disease, and HIV. The common STDs include gonorrhea, chlamydial infection, syphilis, herpes simplex, and human papillomavirus infections.<sup>141–143</sup> Idiopathic

AIDS-related ulcerations have also been described. They typically occur when the CD4 count falls below 200 cells/ $\mu$ L. They are wide mouthed erosions and occur more proximally than benign fistulas, transgressing normal sphincter planes. High-grade dysplasia is more common in patients with HIV and HPV coinfection, and also, there is a higher relapse rate and progression to anal cancer. HIV-positive patients with high HIV loads and/or history of anal dysplasia should be examined by anoscopy and biopsy from condylomata should be sent for histological examination. Anal cancer may be preceded by anal squamous intraepithelial lesions (SILs). Anal SILs were diagnosed in 36% HIV-positive patients and 7% controls in one study.<sup>146,147</sup>

### Miscellaneous

#### HIV AND ABDOMINAL TUBERCULOSIS

Abdominal tuberculosis in HIV-positive patients is a real challenge to the diagnostic acumen and therapeutic skill of a physician. Diagnosis is difficult as symptoms and signs are nonspecific.<sup>148–152</sup> Fever, weight loss, and generalized lymphadenopathy are more common in HIV-positive patients with abdominal tuberculosis, as compared with ascites and jaundice in HIV-negative patients. Tuberculosis should be considered in all HIV-infected patients presenting with diffuse abdominal lymphadenopathy with or without unexplained exudative ascites.<sup>148–152</sup> Some of them may have peripheral lymphadenopathy, especially cervical (Figs. 77.11a, b). Though small bowel involvement is common (77.12a, b, c), involvement of solid organs is more frequently reported. Hepatic, splenic, and pancreatic abscess of tuberculous etiology is more frequently found in patients with advanced HIV disease with low CD4 cell counts.<sup>148–152</sup> Other findings include anemia, intestinal obstruction, psoas abscess, and anorectal involvement.

**Table 77.10:** Causes of Anorectal Disease in HIV-infected Patients

Infections	Neoplasms
<b>Bacteria</b>	Lymphoma
<i>Chlamydia trachomatis</i>	Kaposi sarcoma
<i>Chlamydia trachomatis</i> (L 1-3 strain)	Squamous cell carcinoma
<i>Neisseria gonorrhoeae</i>	Cloacogenic carcinoma

### HIV-ASSOCIATED NON-HODGKIN LYMPHOMA (NHL)

The gastrointestinal tract is a common site of involvement in HIV-associated NHL. The risk factors for this are the same as for HIV-associated extraintestinal NHL. The most common presentations include abdominal pain (77%), weight loss (77%), and gastrointestinal bleeding (38%).<sup>153,154</sup> Computed tomography in patients with NHL typically shows retroperitoneal lymphadenopathy with or without bowel involvement (Fig. 77.13). Life-threatening complications like gastrointestinal bleeding, perforation, and obstruction

**Fig. 77.12b:** Coronal image of CT scan of abdomen showing changes of ileo-caecal tuberculosis. *Courtesy:* Dr. N Kalra, Additional Professor of Radiodiagnosis, PGIMER, Chandigarh.

**Fig. 77.12c:** Colonoscopic view of ulceration and deformity of ileo-caecal area due to tuberculosis.

**Fig. 77.13:** Contrast enhanced CT scan of abdomen showing enlarged retroperitoneal lymph nodes due to lymphoma. *Courtesy:* Dr. Suman Kochhar, Professor of Radiodiagnosis, GMCH, Chandigarh.

occur in 37.5% patients with gastrointestinal tract NHL. The most common sites of involvement include large bowel (46%), ileum (39%), and stomach (23%). Those with HIV-associated gastrointestinal NHL, survive longer and are more likely to respond to therapy than those with extraintestinal HIV-associated NHL. The prognosis of AIDS patients presenting with malignant gastrointestinal lymphoma depends mainly on the presence or absence of previous AIDS defining diseases, but not CD4 counts, lymphoma-associated gastrointestinal complications or histopathological type at the time of diagnosis.<sup>153,154</sup>

### KAPOSI SARCOMA

Kaposi sarcoma is perhaps the most widely associated cutaneous manifestation of AIDS and is the most common malignancy in HIV-infected individuals.<sup>155,156</sup> Approximately 35–40% of HIV-infected patients will develop Kaposi sarcoma, and 40–67% of these lesions will occur in the head and neck region. Kaposi sarcoma lesions are large, red to violet macules. Cutaneous Kaposi sarcoma is usually asymptomatic and is primarily a cosmetic concern. Lesions can become painful if they ulcerate or become secondarily infected. Kaposi sarcoma may also present on mucosal surfaces and in lymph nodes. Epidemiological evidence suggests that KSHV/HHV-8, the causative virus, may be transmitted by faeco-oral route and HHV-8 DNA is detected in rectal samples.<sup>155,156</sup> Treatment is with liposomal anthracyclines, paclitaxel, vinca alkaloids, and cytotoxic agents.

### BACILLARY ANGIOMATOSIS

This vascular cutaneous lesion caused by *Bartonella henselae* is often accompanied by lymphadenopathy, frequently affecting the cervical lymph nodes. Other signs and symptoms include fever, anemia, lung nodules, pleural effusions, ascites, bacteremia, endocarditis, encephalopathy, and involvement of the muscle, bone, liver, or spleen.<sup>30–36</sup> Bacillary angiomatosis is most often found in the later stages of HIV disease when the CD4 count has dropped to below 200/ $\mu$ L. Lymph node and cutaneous lesions have a typical radiological characteristic in which the contrast dramatically enhances the vascular lesions and is followed by a rapid washout. The infection and lesions usually respond to erythromycin, doxycycline, or clarithromycin.

### Summary

Gastrointestinal and hepatobiliary symptoms are among the most frequent complaints in patients with human immunodeficiency virus (HIV) infection and AIDS; whole gastrointestinal tract may be involved. A wide spectrum of illnesses, some caused by HIV itself but more often caused by opportunistic infections and neoplasms are seen in these patients—those with a CD4 count <200 cells/ $\mu$ L are at the greatest risk. *Mycobacterium avium* complex is very uncommon till the CD4 count falls below 50, whereas the risk of candidiasis rises exponentially with fall in CD4 cells <100 cells/ $\mu$ L. Cytomegalovirus is the most common viral infection accounting for 45% of all esophageal ulcers on endoscopy. Diarrhea is a common manifestation occurring in about 50% of the HIV-infected individuals in developed countries and in as high as 80% in developing and underdeveloped countries. A definite cause for diarrhea can be identified in 50–80% of patients with AIDS. Patients with severe immunodeficiency (CD4, count <100 cells/ $\mu$ L) are those most at risk for Cryptosporidium, Microsporidium and CMV disease. Analysis of duodenal/bile juice is a simple, rapid, and effective method. Liver disease in patients with HIV and AIDS presents with varied symptoms including fever, right upper quadrant pain, and hepatomegaly. Almost 90% of patients have abnormalities of the liver enzymes at presentation. HCV, HIV, and hepatitis B virus (HBV) share similar routes of transmission, which include exposure to infected blood or blood products, sexual transmission among heterosexuals and MSM, and vertical transmission from infected mother to her neonate during childbirth. HIV-induced immunosuppression leads to higher HCV RNA levels and accelerated progression to chronic HCV infection. AIDS cholangitis can be an AIDS defining diagnosis. Most patients develop cholangitis years after the initial diagnosis of HIV. Abdominal tuberculosis in HIV positive patients is a real challenge to physicians, as diagnosis is difficult. Such patients have atypical disease more often with increased prevalence of non-intestinal lesions, especially lymphadenopathy and peritoneal disease. Management of all these diseases is many times difficult and expensive; non-availability of specific drugs in the developing countries can be a limitation.

## Renal Manifestations of HIV Infection and AIDS

Frank Post • Rushi Deshpande

### Introduction

It has been more than two and half decades that we know of HIV-related renal disease. The earliest reported was HIV-associated nephropathy (HIVAN) presenting as heavy proteinuria and progressing to end stage renal disease (ESRD) in immunocompromised black persons.<sup>1</sup> Initially the progression of disease to ESRD was so rapid that HIVAN became the third most common cause of ESRD in black population aged between 20 and 64 years.<sup>2</sup> Due to prolonged survival of patients, additional comorbid conditions like diabetes and hypertension accompanied with nephrotoxic effects of highly active antiretroviral therapy (HAART), the spectrum of renal involvement has widened in HIV disease.

The prevalence of renal involvement in HIV-infected individuals varies widely in different populations around the world. The highest incidence was reported in the African-American and Black populations of Africa, so much that HIVAN became the commonest cause of ESRD in these populations. The prevalence amongst other ethnic groups, especially amongst the Caucasians has remained low. Recent data suggest a role of genetic background in the propensity to develop kidney disease. Certain variations in MYH9 and APOL1 genes make the African population uniquely susceptible to kidney disease.<sup>3</sup> Finally, availability of effective HAART has also led to a decline in individuals who develop kidney disease. Despite the large number of HIV-infected individuals in India, HIVAN has been reported only rarely.<sup>4</sup> Most biopsy studies have shown the presence of conditions other than the classically described HIVAN (see below) amongst HIV-infected individuals with kidney disease.

HIV-related renal disease presents as both acute and chronic renal failure involving the glomerulus, the tubular-interstitium, and the vessels. The treatment options include HAART, ACE inhibitors, steroids, and in case of ESRD, renal replacement in the form of intermittent hemodialysis, peritoneal dialysis, and renal transplant in selected patients. With the advent of HAART the progression to ESRD slowed, risk reduced by 40–60% and survival

on dialysis increased from 25% to 75%.<sup>5</sup> Renal diseases in HIV-infected patients still pose a significant morbidity and mortality in spite of adequate treatment. Although renal dysfunction can occur in an HIV-infected patient from a variety of incidental causes, the characteristic lesion that has been associated with HIV is the collapsing form of focal glomerulosclerosis (Table 78.1).

Some of the more common conditions seen during the course of HIV disease are described.

**Table 78.1:** Incidental Renal Disorders in HIV Infection

<b>Acute renal failure</b>
Acute tubular necrosis from hypovolemia, hypoxia, and toxic injuries. Allergic interstitial nephritis as a result of drugs. Severe hypoalbuminemia as a result of massive proteinuria Post-infection immune complex glomerulonephritis Crystal-induced renal failure (sulfadiazine, acyclovir, indinavir, etc.) Plasmacytic interstitial nephritis Hemolytic uremic syndrome and thrombotic thrombocytopenic purpura
<b>Chronic HIV nephropathies</b>
HIV-associated nephropathy (HIVAN) HIV immune complex kidney disease (HIVICK) Thrombotic microangiopathy
<b>Fluid, electrolyte, and acid–base derangements</b>
Hyponatremia Inappropriate secretion of antidiuretic hormone Hypokalemia and hyperkalemia Type IV renal tubular cell acidosis Hypomagnesemia
<b>Infections in the kidney</b>
Renal microabscesses from bacterial infections Tuberculosis Cytomegalovirus lesions Cryptococcus, Aspergillus, and other fungal diseases
<b>Infiltrative diseases of the kidney</b>
Lymphoma Kaposi sarcoma Amyloidosis Calcification

## Acute Renal Failure

The HAART era has seen the maximum rise in acute renal failure (ARF) in HIV patients. The incidence is about 20% in hospitalized patients with a consequent increase in hospital mortality.<sup>6</sup> Commonest etiology cited is drug induced, commonly used drugs like indinavir, tenofovir, and atazanavir require dose adjustment. Hemolytic uremic syndrome and HIVAN remain important causes of ARF in HIV patients. Others include HIV patients with liver or chronic kidney disease and opportunistic infections. In HIV patients with ARF, co-infection with HCV, underlying chronic kidney disease, old age, and more advanced disease are known risk factors with poor outcome.<sup>7</sup> Care must be taken to avoid hypotension and nephrotoxic agents and also to adjust dosage of renally excreted medications.

## Chronic HIV Nephropathies

Chronic kidney disease in HIV patients majorly includes HIVAN, HIV immune complex kidney disease (HIVICK) and thrombotic microangiopathies.

### HIV-ASSOCIATED NEPHROPATHY (HIVAN)

Following diabetes and hypertension, it is the third commonest cause of ESRD in young and middle-aged African Americans. Ratio of the diseased in the black population as compared to the white is 12:1.<sup>8</sup>

HIVAN presents with:

1. Nephrotic range proteinuria.
2. Edema due to hypoalbuminemia.
3. Hypercholesterolemia.
4. Hypertension—not a very common feature even in advanced disease.

Investigations show:

1. Presence of renal tubular epithelial cells in urinary sediment.
2. Normal or large echogenic kidneys on ultrasound.<sup>9–11</sup>
3. Microhematuria.
4. Sterile pyuria with sub-nephrotic proteinuria is also been reported in some patients.
5. Early HIVAN may present as microalbuminuria with normal glomerular filtration rate (GFR).

### Pathological Hallmark (Fig. 78.1 and 78.2):

1. Presence of focal segmental glomerulosclerosis (FSGS) on light microscopy.
2. Involves all parts of the kidney with collapse of glomerulus.
3. Podocyte proliferation, tubular atrophy with microcystic dilatation.<sup>12</sup>
4. Mononuclear cell infiltration with edema and fibrosis of interstitium.

**Fig. 78.1:** HIVAN. Light microscopy showing collapsing variant of FSGS: H&E ×400.

**Fig. 78.2:** HIVAN. Light microscopy showing collapsing variant of FSGS: PAS ×200.

5. Mesangial hyperplasia (more common in children<sup>13,14</sup>).
6. C3 and IgM are seen on immunofluorescence.
7. EM shows retraction of glomerular basement membrane with no immune deposits and tubular reticular inclusions in endothelial cells (Fig. 78.3).

Isolation of HIV-1 from tubular epithelial cells, glomerular epithelial cells, and interstitial leukocytes has proved the direct affection of HIV-1 of the kidney.<sup>15</sup> Podocytes undergo proliferation and dedifferentiation because of expression of maturity markers including WT-1 and synaptopodin.

Patients of African heritage (black ethnicity) and those who have advanced HIV disease are at high risk.<sup>16</sup> Severity of histological damage of kidneys remains an important predictor of outcome.

Treatment mainly constitutes:

1. HAART therapy: In a study it was shown that patients initiated on early HAART did not develop HIVAN.<sup>17</sup>

**Fig. 78.3** EM showing retraction of glomerular basement membrane with no immune deposits and tubular reticular bodies in endothelial cells:  $\times 10,000$ .

In another study, suppression of HIV replication was observed in biopsy-proven HIVAN patients, who were initiated on early HAART.<sup>18</sup> FSGS may respond to corticosteroid therapy with short-term improvement in clinical parameters.

2. ACE inhibitors modulate matrix production and mesangial cell proliferation, preventing proteinuria and slow the progression to renal failure.<sup>19–21</sup>
3. Renal transplant remains a viable option in selected patients.<sup>22,23</sup>

## HIV-Associated Immune-Mediated Glomerulopathies

### IMMUNE MEDIATED

Deposition of immune complexes which contain HIV antigen and antibody to gp 120 HIV<sup>24</sup> cause HIV immune complex kidney disease (HIVICK). Deposits mainly contain IgG, C1q, and C3.

These deposits are seen in mesangial, sub-endothelial, intra- and epimembranous deposits. Histologically, these lesions are characterized by endocapillary proliferation with parietal fibrinoid deposits in multiple sites. Resemblance to lupus glomerulonephritis is seen in areas of intense deposits. As compared to HIVAN, progression to renal failure is slow and interstitial infiltrates contain increased number of “B” cells.

### IGA NEPHROPATHY

IgA nephropathy in HIV-infected patients is not uncommon. They have mild urinary abnormalities and less involvement of the glomerulus, with some mesangial deposits and mesangial hypertrophy.<sup>25</sup> In these patients, immune complexes have anti-idiotypic IgA reacting with anti gp41 IgG.<sup>26</sup>

## Co-infections

Patient with HCV and HIV co-infection have poor outcome. There is increasing prevalence of HCV co-infection in HIV patients probably because of increasing numbers of intravenous drug abusers in the HIV positives. Patient presents with renal insufficiency, microscopic hematuria with acute urine sediment, hypertension, and nephrotic range proteinuria without hypercholesterolemia. Decreased complement levels and cryoglobulinemia were seen in one third of the patients. Patients rapidly progress to renal failure requiring dialysis.

The commonest renal biopsy finding is of membranoproliferative glomerulonephritis (MPGN) and less frequently membranous glomerulopathy. Hypocomplementemia, cryoglobulinemia, hypertension, and microscopic hematuria differentiate HCV-associated glomerulonephritis (GN) in HIV patient from HIVAN but renal biopsy is essential.<sup>27</sup>

Renal amyloidosis<sup>28</sup> and fibrillary immunotactoid GN<sup>29</sup> are infrequently observed in a HIV-infected patient.

## HIV-Associated Thrombotic Microangiopathy

Boccia et al.<sup>30</sup> first described thrombotic microangiopathies involving the kidney in HIV-positive patients. The prevalence is variably reported worldwide.

Microangiopathic hemolytic anemia with renal insufficiency, thrombocytopenia, fever, and neurological changes are commonly seen, though thrombocytopenia is predominant in thrombotic thrombocytopenic purpura (TTP), microangiopathic hemolytic anemia and renal failure predominates in hemolytic uremic syndrome (HUS). They are more common in young (mean age 35 years) with male (80%) predominance. Absence of massive proteinuria differentiates it from HIVAN and immune-mediated diseases.<sup>31</sup>

Pathogenesis involves direct endothelial damage, renal cellular apoptosis, and von Willebrand factor—cleaving protease inhibition. Histologically, it shows platelet fibrin thrombi in glomerular capillaries, renal arterioles, and inter-lobular arteries, endothelial cell edema, arterial intimal edema, fibrinoid necrosis, mesangiolysis, and onion skin lesions. Immunofluorescence shows fibrin and fibrinogen in arterioles and the glomerular deposits of fibrinogen, C1q, C3, C4, IgA, and IgM and light chains. On electron microscopy tubuloreticular lesions are seen in endothelial cells in blood vessels.<sup>32</sup>

Treatment options include HAART with plasmapheresis and splenectomy in refractory cases. Despite aggressive treatment HIV-TTP/HUS has high mortality early in the disease.<sup>33</sup>

## Electrolyte Disorders

1. Hyponatremia is seen in 40% of the patients and is commonly due to loss through GI tract, adrenal insufficiency, and syndrome of inappropriate antidiuretic hormone hypersecretion (SIADH) secondary to pulmonary and central nervous system infections.<sup>34</sup>

- Hyperkalemia is seen in affected patients with adrenal insufficiency, ARF and pentamidine therapy.
- Hypokalemia is seen in patients with GI losses due to diarrhea.
- Metabolic alkalosis is observed in patients with prolonged vomiting.
- Patients on pentamidine therapy have hypomagnesemia and symptomatic hypocalcemia due to renal magnesium wasting.<sup>35</sup>

## Renal Infections

Multidrug-resistant tuberculosis is highly prevalent in HIV-positive patients.<sup>36</sup> Extra pulmonary infection like renal tuberculosis is seen frequently, which is rather difficult to diagnose and treat due to drug interactions. Opportunistic infections like histoplasmosis, aspergillosis, toxoplasmosis, cytomegalovirus (CMV) and *Pneumocystis jiroveci* may affect the kidney.<sup>37</sup>

CMV is known to cause acute tubular necrosis (ATN) and is also postulated to cause HIVAN.<sup>38</sup>

## Nephrotoxic Effects of HAART (Table 78.2)

Many antiretroviral drugs are implicated to cause renal injury; most frequently indinavir and tenofovir have been implicated. Indinavir causes nephrolithiasis and interstitial nephritis due to crystallization in the urinary tract. Progression to chronic kidney disease is not uncommon but usually it resolves with hydration and drug discontinuation.<sup>39</sup> Tenofovir is implicated in the development of ARF, progressive renal failure, renal tubular acidosis, Fanconi syndrome, nephrogenic diabetes insipidus, hypokalemia, osteomalacia, and urinary concentration defects.<sup>40</sup> Discontinuation of the drug usually resolves the renal failure. Tenofovir with didanosine and boosted PIs, old age, advanced disease, low body mass are

**Fig. 78.4:** Drug-induced interstitial nephritis showing inflammatory mononuclear cells in the interstitium H&E × 400.

risk factors for renal impairment.<sup>41</sup> Atazanavir is known to cause kidney stones, acute interstitial nephritis (Fig. 78.4) and chronic kidney disease.<sup>42</sup>

## Dose Modification of ARV in Adults with Renal Dysfunction (Table 78.3)

### Nucleoside/tide Reverse Transcriptase Inhibitors (NRTIs)

Most NRTIs, including didanosine (ddI), emtricitabine, stavudine (d4T), tenofovir (TFV), zalcitabine, and lamivudine are eliminated primarily unchanged in the urine. Zidovudine and abacavir undergo substantial hepatic biotransformation, and

**Table 78.2:** Antiretrovirals Shown to be Potentially Nephrotoxic<sup>43</sup>

Drug	Reported nephrotoxicity	Risk factor(s)
Abacavir	Acute renal failure, interstitial nephritis (rare)	...
Atazanavir	Case reports of nephrolithiasis, interstitial nephritis, reversible renal failure	Not established
Didanosine	Tubular dysfunction (rare)	...
Efavirenz	Single report of hypersensitivity reaction	...
Enfuvirtide	Single report of glomerulonephritis	...
Indinavir	Nephrolithiasis, crystalluria, dysuria, papillary necrosis, acute renal failure	Concomitant treatment with low-dose ritonavir; for nephrolithiasis, urine pH >6, low lean body mass, treatment with trimethoprim-sulfamethoxazole or acyclovir, chronic infection with hepatitis B or hepatitis C virus, warm environmental temperature, high indinavir concentration
Lamivudine	Tubular dysfunction (rare)	...
Ritonavir	Reversible renal failure, but nephrotoxicity not definitely established	Concomitant treatment with nephrotoxic drugs, underlying renal pathology
Stavudine	Tubular dysfunction (rare)	...
Tenofovir	Tubular toxicity, Fanconi syndrome (rare), decreased glomerular filtration rate	Low body weight, impaired baseline renal function, concomitant treatment with potentially nephrotoxic drugs

**Table 78.3:** Nucleoside or Nucleotide Dosage Adjustment for HIV-infected Patients with Reduced Glomerular Filtration Rate

Antiretrovirals	Daily dosage	Dosing in the case of renal insufficiency
<b>Nucleoside reverse-transcriptase inhibitor</b>		
Abacavir	300 mg PO BID	No need for dosage adjustment
Didanosine	If >60 kg, 400 mg PO QD; if <60 kg, 250 mg QD	For CrCl of 30–59 mL/min, 200 mg for weight >60 kg and 125 mg for weight <60 kg For CrCl of 10–29 mL/min, 125 mg for weight >60 kg and 100 mg for weight <60 kg For CrCl of <10 mL/min, 125 mg for weight >60 kg and 75 mg for weight <60 kg For patients undergoing CAPD or HD, use same dose as for CrCl <10 mL/min
Emtricitabine	200 mg Oral capsule PO QD or 240 mg (24 mL) oral solution PO QD	For CrCl of 30–49 mL/min, capsule of 200 mg every 48 h or solution of 120 mg every 24 h For CrCl of 15–29 mL/min, capsule of 200 mg every 72 h or solution of 80 mg every 24 h For CrCl of <15 mL/min, capsule of 200 mg every 96 h or solution of 60 mg every 24 h or HD*
Lamivudine	300 mg PO QD or 150 mg PO BID	For CrCl of 30–49 mL/min, 150 mg QD For CrCl of 15–29 mL/min, 150 mg one time, then 100 mg QD For CrCl of 5–14 mL/min, 150 mg one time, then 50 mg QD For CrCl of <5 mL/min, 50 mg one time, then 25 mg QD or HD*
Stavudine	If >60 kg, 40 mg PO BID; if <60 kg, 30 mg PO BID	For CrCl of 26–50 mL/min, 20 mg every 12 h for weight >60 kg and 15 mg every 12 h for weight <60 kg For CrCl of 10–25 mL/min, 20 mg every 24 h for weight >60 kg and 15 mg every 24 h or HD*
Tenofovir	300 mg PO QD	For CrCl of 30–49 mL/min, 300 mg every 48 h For CrCl of 10–29 mL/min, 300 mg twice weekly for ESRD, 300 mg every 7 days or HD*
Tenofovir plus emtricitabine	1 Tablet PO QD	For CrCl of 30–49 mL/min, tablet every 48 h For CrCl <30 mL/min, not recommended
Zidovudine	300 mg PO BID	For “severe” renal impairment or HD*, 100 mg TID or 300 mg QD
<b>Non-nucleoside reverse-transcriptase inhibitor</b>		
Delavirdine	400 mg PO TID	No dosage adjustment necessary
Efavirenz	600 mg PO QD, 1 tablet PO QD	No dosage adjustment necessary; Atripla not recommended if CrCl <50 mL/min
Efavirenz-tenofovir-emtricitabine	600 mg PO QD, 1 tablet PO QD	Atripla not recommended if CrCl <50 mL/min
Nevirapine	200 mg PO BID	No dosage adjustment necessary
<b>Protease inhibitor</b>		
Atazanavir	400 mg PO QD	No dosage adjustment necessary for patients not requiring HD
Darunavir	600 mg Plus 100 mg ritonavir PO BID	No dosage adjustment necessary
Fosamprenavir	1400 mg PO BID	No dosage adjustment necessary
Indinavir	800 mg PO every 8 h	No dosage adjustment necessary
Lopinavir-ritonavir	400-100 mg PO BID or 800-200 mg PO QD (QD for treatment-naïve patients only)	No dosage adjustment necessary
Nelfinavir	1250 mg PO BID	No dosage adjustment necessary
Ritonavir	600 mg PO BID	No dosage adjustment necessary
Saquinavir soft gel cap	1200 mg TID	No dosage adjustment necessary
Tipranavir	500 mg PO BID; with ritonavir 200 mg PO BID	No dosage adjustment necessary
<b>Entry inhibitor</b>		
Enfuvirtide	90 mg Subcutaneously every 12 h	No dosage adjustment necessary
Maraviroc	The recommended dose differs on the basis of concomitant medications because of drug interactions: 150 mg, 300 mg, or 600 mg BID	No dosage recommendation; use with caution; patients with CrCl <50 mL/min should receive maraviroc and CYP3A inhibitor only if potential benefit outweighs the risk
<b>Integrase inhibitor</b>		
Raltegravir	400 mg BID QD	No dosage adjustment

**Note:** Adapted from US Department of Health and Human Services guidelines for the use of antiretroviral agents in HIV-1-infected adults and adolescents.

Atripla, efavirenz-emtricitabine-tenofovir; BID, twice per day; CAPD, continuous ambulatory peritoneal dialysis; CrCl, creatinine clearance level; ESRD, end-stage renal disease; HD, hemodialysis; HD\*, dose after HD; PO, orally; QD, every day; TID, 3 times per day.

therefore may require less or no dose reductions. Tenofovir may be used in ESRD patients since it can be dosed once weekly, thus decreasing pill burden and reducing the annual cost.

Fixed-dose co-formulations are to be avoided in patients with significant renal dysfunction because renal excretion of all the components is not identical.

### Non-nucleoside Reverse Transcriptase Inhibitors (NNRTIs)

Dose modifications are not required for patients with renal insufficiency as NNRTIs undergo hepatic metabolism.

### Protease Inhibitors (PIs)

Available PIs (atazanavir, darunavir, fosamprenavir, indinavir, lopinavir/ritonavir, nelfinavir/ritonavir, saquinavir, and tipranavir) are highly metabolized in the liver. Dose adjustment is not required for patients with renal insufficiency. Indinavir is associated with nephrolithiasis due to precipitation in the urinary tract. Atazanavir has also been associated with nephrolithiasis and is the only protease inhibitor that has a specific warning against use in patients on hemodialysis as there is 40% reduced absorption relating to lower gastric pH in these patients.

### Entry Inhibitors

Maraviroc is a CCR5 inhibitor, with 25% of the drug being eliminated through the kidneys. Maraviroc should be used with caution in patients with renal dysfunction; if the creatinine clearance is less than 50 mL/min. Combination of maraviroc and ritonavir should only be used "if the potential benefit outweighs the risk." Fusion inhibitor enfuvirtide requires no dose modification in patients with renal dysfunction.

### Integrase Inhibitors

Raltegravir is metabolized via UGT1A1 glucuronidation, hence is a safe drug requiring no dosing adjustments for patients with renal or hepatic dysfunction.

### TIMING OF DOSES FOR PATIENTS ON HEMODIALYSIS

Antiretroviral drugs that are not likely to be dialyzed are zidovudine, lamivudine, abacavir, efavirenz, etravirine, delavirdine, nelfinavir, saquinavir, indinavir, ritonavir, lopinavir, and fosamprenavir. Postdialysis dosing results in optimal serum concentrations. Drugs like didanosine, stavudine, and zalcitabine are most likely to be removed by dialysis so are best avoided or dosed post dialysis.

### Renal Transplantation in Patients with HIV Infection

HIV infection was a contraindication to transplantation in the past because of limited supply of donor organs, possibility of

exacerbation of the immunocompromised state by administration of additional immunosuppressants, unknown long-term outcome and risk of transmission to the staff members.<sup>44</sup>

Changes in the trend were seen by the advent of HAART as it has turned HIV into more of a chronic infection. Studies have shown greater than 80% graft survival at 1–3 years after kidney transplantation in patients on HAART. Rate of acute graft rejection is more compared to HIV-negative patients. Progression of liver disease is a major concern in renal transplant recipients with co-infection of HIV and HCV.<sup>45,46</sup>

### PROPOSED CRITERIA FOR RENAL TRANSPLANTATION<sup>47,48</sup>

#### Inclusion Criteria

- Meeting standard criteria for inclusion in renal transplantation list.
- CD4+ T-cell count  $\geq 200/\mu\text{L}$  at any time in the 16 weeks before transplantation.
- No change in antiretroviral regimen for 3 months before transplantation.
- Primary medical care provider has expertise in HIV treatment.
- Ability and willingness to comply with immunosuppression protocol and antiretroviral therapy.
- Ability and willingness to undergo prophylaxis for Pneumocystis pneumonia, herpes virus, and fungal infection.
- If hepatitis C co-infection is present, ability, and willingness to undergo frequent post-transplantation monitoring including hepatitis C treatment as mandated by medical care provider and collection of liver biopsy samples.
- If a history of pulmonary coccidioidomycosis exists, patient must be disease free for at least 5 years before transplantation.
- If a history of neoplasms such as cutaneous Kaposi sarcoma, *in situ* anogenital carcinoma, adequately treated basal or squamous cell carcinoma of the skin or solid tumors treated with curative therapy exists, the patient must be disease free for at least 5 years before transplantation.
- If a history of renal cell carcinoma exists, patient must be disease free for at least 2 years before transplantation.
- Ability to provide informed consent. For children under the age of 7 years, only the parent can provide consent. For children aged 7–12 years, the parental or legally responsible person must provide informed consent and the minor must sign an assent. In the case of a minor between ages 13 and 18 years, the minor and parent(s) must provide informed consent.
- Female candidates of child-bearing potential must have a negative serum human chorionic gonadotropin chain beta pregnancy test 14 days before transplantation. All candidates must practice barrier contraception.

#### Exclusion Criteria

- Age <1 year.
- Detectable HIV-1 RNA.

- History of progressive multifocal leukoencephalopathy, chronic intestinal cryptosporidiosis of at least 1 month duration, lymphoma (Burkitt, immunoblastic, or of brain).
- History of multidrug-resistant fungal infection (e.g., resistant *Candida krusei* or *Candida glabrata* infection) not expected to respond to available oral antifungal agents.
- History of any neoplasm except those specified in the inclusion criteria.
- Substance use as per local transplantation policy.
- Advanced cardiac or pulmonary disease as per local transplantation policy.
- Anatomic abnormalities precluding transplantation.
- Use of interleukin 2 or granulocyte-macrophage colony-stimulating factor in the 6 months before transplantation.
- Cirrhosis on liver biopsy in patients with hepatitis C co-infection, unless candidate is being listed for combined liver and kidney transplant.
- Substantial wasting and/or malnutrition.
- Concomitant conditions that, in the judgment of care providers, preclude transplantation or immunosuppression.

### IMMUNOSUPPRESSIVE STRATEGIES

Initially in HIV patients, regimen of steroids, calcineurin inhibitors (CNI), and mycophenolate mofetil (MMF) were used for immunosuppressive regimens for maintenance therapy.<sup>49</sup> However organ recipients with HIV can amount to alloimmune response,<sup>50</sup> and renal transplant recipients have higher rejection rates. Hence induction therapy with interleukin 2 receptor inhibitor (to deplete CD4+ T cells) is used which successfully reverses aggressive rejection in several patients.<sup>51,52</sup>

Antiretroviral properties are seen in most of the post-transplantation maintenance immunosuppressive drugs like mycophenolate mofetil, CNI, and sirolimus.

Mechanism of action of MMF is by guanosine nucleoside depletion and imparts virostatic effect.<sup>53,54</sup> CNI interferes with HIV protein function.<sup>55</sup> Cyclosporine and tacrolimus have well-documented antiretroviral effects through selective inhibition of infected cell growth.<sup>56,57</sup> Sirolimus causes suppression of T-cell activation, suppression of antigen presenting cell function, disruption of infective virion replication and decrease of expression of C-C chemokine receptor type 5 on monocytes and lymphocytes.<sup>58</sup>

### Drug Interactions

1. NNRTIs induce CYP3A4, hence NNRTIs, like nevirapine and efavirenz, administered with CNI lead to decrease in CNI levels.<sup>59,60</sup>
2. Patients on PIs and cyclosporine require only 20% of immunosuppressant dose as compared to non-HIV renal transplant patients. The pharmacologic interactions are well documented in a study describing the pharmacokinetics and dosing modifications of cyclosporine, sirolimus, and tacrolimus in 35 liver or kidney transplant recipients on NNRTIs, PIs or both.<sup>61</sup>

3. Ritonavir boosts the plasma levels of other PIs (ritonavir inhibits p-glycoprotein & CYP3A4). In patients on tacrolimus or sirolimus dosing interval is increased fivefold and immunosuppressant dose decreased markedly. Co-administration of CNI and PIs leads to increase in levels of CNI (P-glycoprotein & CYP3A4 activity).
4. Patients on steroids are often co-administered a proton pump inhibitor which reduces intestinal absorption of PI atazanavir, hence avoid this combination,<sup>62,63</sup> or the treatment to be boosted by the administration of ritonavir.<sup>64</sup>
5. *In vitro* evidence suggests that MMF is antagonistic to the anti-HIV replication effects of zidovudine and stavudine,<sup>65</sup> so these drug combinations should probably be avoided. Zidovudine and MMF can lead to added myelosuppressive effect.
6. Extreme bradycardia was noted with lopinavir/ritonavir given to patients on metoprolol and lacidipine due to enzyme induction.<sup>66</sup>
7. Dolutegravir S/GSK1349572 represents a new unboosted integrase inhibitor currently under development, which is given once-daily. It has a low pharmacokinetic variability and predictable exposure-response relationship.<sup>67</sup>
8. Pharmacokinetic interactions are anticipated when voriconazole is administered with HIV protease inhibitors and NNRTIs because of enzyme induction causing decreasing trough levels of these drugs.<sup>68</sup>
9. Anti-HIV drug efavirenz levels are found to be high in patients on antituberculars and this is due to increased susceptibility of the CYP2B6 variant to inhibition by one or more of the anti-TB drugs or inhibition of an alternative pathway (e.g., CYP2A6).<sup>69</sup>

### Summary

Kidney disease is an important complication of HIV infection, especially in those with advanced disease. Its development is heavily influenced by the genetic background and availability of effective therapy in early stages. We must think beyond HIVAN when we discuss about HIV and renal diseases. HIV-associated kidney disease is characterized by some unique pathologic characteristics, the most recognizable of which are collapsing focal segmental glomerulosclerosis. Almost any renal syndrome including electrolyte derangements can be encountered in these individuals. There is no specific therapy and prevention using early HAART remains the best approach to prevent kidney disease. In the era of HAART therapy drug interactions and drug-induced interstitial nephritis must be kept in mind. Drug dosages should be adjusted as per creatinine clearance and nephrotoxic drugs should be avoided. Drug interactions between antiretrovirals and various other medications needed for management of kidney disease need attention. All forms of renal replacement therapy including kidney transplantation can be offered to individuals who develop ESRD. Careful and scientific approach utilizing the wide armamentarium against HIV and renal disease, one can significantly reduce morbidity and mortality in these patients.

# HIV and Endocrine Manifestations

Shiva Prakash • Ravinder Goswami

## 79

Since the introduction of antiretroviral therapy, the morbidity and mortality from HIV infection has decreased. HIV infection is now a manageable infection that can be controlled with drugs. However, adrenal, gonadal, thyroid, bone, and metabolic abnormalities like diabetes mellitus and lipodystrophy are common in HIV-infected patients. These occur because of the result of HIV itself, immunologic-cytokine mediated factors, antiretroviral drugs and opportunistic infections or the interaction of these factors.

### Adrenal Dysfunction

The hypothalamic-pituitary-adrenal axis involvement is common in patients with HIV-infection. Usually the involvement is subclinical, and clinically evident adrenal insufficiency is uncommon because symptoms do not appear until more >80% of gland has been destroyed.<sup>1</sup> The extent of necrosis reported in autopsy findings of cytomegalovirus (CMV) adrenalitis, rarely exceeds 60%. Adrenocortical antibodies are detected in a substantial proportion of patients with AIDS due to nonspecific B cell activation.<sup>2</sup> Adrenal insufficiency usually occurs in the advanced stages of infection and can be primary due to direct involvement of the adrenal or secondary alteration due to involvement of hypothalamic pituitary adrenal axis.

#### CAUSES OF ADRENAL INSUFFICIENCY

##### (A) Primary

- Infections: Tuberculosis, HIV, cytomegalovirus, cryptococcus, toxoplasmosis, histoplasmosis.
- Tumor: Kaposi sarcoma, lymphoma, hemorrhage.
- Medications: Ketoconazole, fluconazole, rifampicin, etomidate.

##### (B) Secondary/tertiary

- Infection/Infiltration: Tuberculosis, sarcoidosis, hemochromatosis.
- Medications: Megestrol, exogenous steroids.
- Tumors, trauma, isolated ACTH deficiency.

On the contrary, elevated basal cortisol level and lower dehydroepiandrosterone (DHEA) levels in the absence of Cushing syndrome are common in HIV-infected patients. These are attributed to the shift from Th1 to Th2 immunologic response.<sup>3</sup> Some patients with AIDS have a syndrome of peripheral cortisol resistance due to acquired abnormalities of glucocorticoid receptor (GR), characterized by increase in GR density, decrease in GR affinity for the substrate, high serum cortisol with low ACTH, Addisonian features and increased production of IFN- $\alpha$ .<sup>4</sup> Basal aldosterone levels are usually low in HIV-infected individuals. Protease inhibitors may cause mildly elevated basal cortisol or 24-hour urine cortisol level. However, cortisol levels are suppressed normally in response to dexamethasone.

The principle metabolic route of glucocorticoids is via the cytochrome p450 3A4 enzyme. Ritonavir, a protease inhibitor (PI) used in the treatment of HIV infection, is an extremely potent inhibitor of cytochrome p450 3A4 activity. When both ritonavir and inhaled fluticasone are administered together there is an increased risk of developing Cushing syndrome with secondary adrenal suppression. These effects are not limited to ritonavir alone and can be seen with other PIs also. Fluticasone is highly lipophilic, has greater volume of distribution, and prolonged receptor occupancy. The iatrogenic Cushing syndrome may be mistaken for HIV-lipodystrophy and result in delayed diagnosis. In HIV-infected individuals with asthma, administration of both PIs and fluticasone needs to be avoided.<sup>5</sup>

### Androgen Deficiency

Hypogonadism is prevalent among HIV-infected men with low weight and wasting. In AIDS-related wasting, the prevalence of hypogonadism is about 50%. Recent reports have shown hypogonadism to be present in 20% of men on highly active antiretroviral therapy (HAART).<sup>6</sup> The usual cause of hypogonadism among men is "hypogonadotrophic hypogonadism" which is often due to multiple factors such as malnutrition, severe illness and drugs such as opiates, megestrol acetate, steroids, and anabolic steroids. Hypogonadism may also be due to a primary testicular

etiology, which can be due to infections or drugs. Among women, inadequate adrenal androgen secretion in association with severe illness may contribute to reduced overall androgen levels.<sup>7</sup>

Increased serum hormone binding globulin (SHBG) levels are seen in HIV-infected patients (30–55%). This results in relative increases in total testosterone levels that may over estimate bioavailable testosterone. Measurement of free testosterone, unbound to SHBG rather than total testosterone is advisable when hypogonadism is being evaluated in HIV-infected patients. Hyperprolactinemia has been reported in 21% of HIV-infected men with stable HIV disease and was significantly associated with opioid use and increased CD4 count but not with changes in body composition or gynecomastia.<sup>8</sup> Increased serum prolactin in association with galactorrhea has also been described among HIV-infected patients treated with PIs, both men and women.<sup>9</sup> Hypogonadism is associated with reduced muscle mass, decreased strength, and decreased functional status. Reduced androgen levels are also associated with bone loss and depression. Treatment of hypogonadal HIV-infected men has been shown to increase muscle mass, strength, and improve bone mass and depression indices.<sup>10</sup>

## Thyroid Dysfunction

Thyroid function abnormalities are common in HIV-infected patients. In HIV-infected patients, thyroxine binding globulin (TBG) levels are often elevated and correlate inversely with CD4 cell counts. Total T4 may not be reliable when assessing thyroid function due to increased protein binding. Direct measurement of freeT4 (FT4) is essential in HIV-infected individuals. Isolated low FT4 levels with concurrent normal TSH levels are found frequently among HIV-infected individuals, with a prevalence varying between 1.3% and 6.8%.<sup>11</sup> Pediatric HIV-infected patients on HAART were found to have an increased prevalence of isolated low FT4 levels (31%). Isolated low FT4 levels have been associated with didanosine, stavudine, and zidovudine. The mechanism causing low FT4 levels have not been elucidated. The clinical significance of a low FT4 level is unclear, because these patients do not have hypothyroid symptoms. Follow-up with annual thyroid function testing is advocated.<sup>12</sup>

The prevalence of hypothyroidism is increased in HIV infected individuals (0–2.6%) compared to general population (0.3%). Onset of Hashimoto thyroiditis does not appear to be common during HAART-associated immune reconstitution. Subclinical hypothyroidism is common, especially among HIV-infected patients who are receiving HAART with a prevalence of between 3.5 and 12.2%.<sup>13</sup> The prevalence of subclinical hypothyroidism is higher in men and in those with low CD4 cell count. Thyroid peroxidase (TPO)-autoantibodies are only rarely associated with subclinical hypothyroidism implicating nonautoimmune mechanisms.<sup>14</sup>

In persons with HIV infection, Graves disease may occur after immune reconstitution from HAART. A retrospective study found a median period of 20 months from initiation of HAART to the development of Graves' disease and a parallel increase of

CD4-cell count. This may be related to the resurgence of Th1 cytokine profile.<sup>15</sup> Transient Graves' disease has also been observed among HIV-infected patients with naïve CD4 cell expansion driven by IL-2 treatment.<sup>16</sup>

The most common thyroid function pattern during non-thyroidal illness is reduced T3 level, elevated reverse T3 (rT3) level, variable FT4 level, relatively normal/decreased thyroid stimulating hormone (TSH) level. However, some studies have shown that rT3 levels do not rise with decreasing T3 levels. Patients with progressive disease therefore, paradoxically have reduced T3 levels, decreased rT3 level, and increased TBG levels with increasing severity of illness.<sup>17</sup> During recovery from illness, the TSH levels may increase temporarily mimicking subclinical hypothyroidism. Among HIV-infected populations, non-thyroidal illness was seen in 16% of patients with terminal AIDS before the HAART era. AIDS-related conditions that cause thyroid dysfunction include thyroiditis due to *Pneumocystis jirovecii* infection, cryptococcus infection, visceral leishmaniasis, and suppurative bacterial infection of the thyroid.<sup>18</sup> Rarely, lymphoma and Kaposi sarcoma can infiltrate the thyroid and impair its function. CMV rarely causes thyroid disease. However in the HAART era, thyroiditis secondary to infectious etiology are rare.

Thyroid function testing in HIV infected patients should be done when symptoms of hypothyroidism or hyperthyroidism, osteopenia, dyslipidemia, depression, and atrial fibrillation are seen.

## Bone Loss

Reduced bone mineral density (BMD) is prevalent in primary HIV infection and may be associated with increased age, lower body mass index (BMI), lower TSH level, and higher levels of HIV-1 viremia.<sup>19</sup> Multiple cross-sectional studies have shown an increased prevalence of reduced BMD among HIV-infected individuals.<sup>20–22</sup> A systematic review revealed 6.4-fold increased odds of reduced BMD in HIV infected patients and 3.7-fold increased odds of osteoporosis compared to HIV uninfected controls.<sup>21</sup> A recent population based study confirmed a higher prevalence of bone fractures in HIV infected men and women compared to HIV uninfected controls.<sup>22</sup>

In ambulatory HIV positive men without wasting, BMD at the lumbar spine was marginally lower (3%) in ART naïve men than in age-healthy controls. The initiation of antiretroviral therapy results in significantly reduced BMD. Lumbar spine BMD was markedly lower in HIV positive men receiving PIs in comparison with HIV positives not receiving PIs and HIV negative controls.<sup>23</sup> However subsequent studies have given conflicting results.<sup>24</sup> Tenofovir (thymidine analog) has been reported to result in pronounced decline in BMD and may impair phosphate reabsorption in proximal renal tubules, resulting in osteomalacia.<sup>25</sup> Patients on long term treatment with antiretroviral therapy have been found to have stable BMD, suggesting that immunologic changes occurring during drug initiation may be contributory.<sup>26</sup>

Chronic HIV infection causes an increased synthesis of bone-resorbing TNF- $\alpha$ , IL-6 cytokines. These cytokines and viral proteins (Vpr, gp120) stimulate both osteoclast activity and decrease osteoclast apoptosis, thereby increasing bone resorption.<sup>27</sup> Most studies support the observation of increased bone turn over in HIV infected patients on ART. Serum levels of RANKL were significantly higher in HIV-positive men on ART in comparison to those who were not receiving ART. Serum osteocalcin decreases and C-telopeptide increases with advancing severity of HIV disease.

Low bodyweight, malnutrition, age, hypogonadism, drug abuse, drugs, alcohol, and smoking are other risk factors associated with bone loss.<sup>28</sup> Patients with advanced disease may have low 1,25(OH)<sub>2</sub>D levels due to impaired 1 $\alpha$ -hydroxylase activity.<sup>29</sup> Currently there are no firm recommendations for the treatment of osteoporosis for men or persons with HIV. Adequate intake of calcium and vitamin D should be part of any treatment regimen involving bone health.

## Electrolyte and Water Imbalance

Hyponatremia is the most commonly seen electrolyte abnormality in HIV-infected patients with a prevalence of 30–60% in hospitalized patients.<sup>30</sup> Hyponatremia has also been associated with increased mortality when compared to a normonatremic group. The usual outpatient cause of hyponatremia is diarrhea and vomiting. In hospitalized patients, the usual cause of hyponatremia is syndrome of inappropriate ADH secretion (SIADH), secondary to infectious causes related to pulmonary and neurological system.<sup>31</sup> Hypokalemia is commonly related to drugs used in the treatment of opportunistic infections. Amphotericin B and itraconazole are the usual causes. Tenofovir has been associated with Fanconi syndrome, hypokalemia, and nephrogenic diabetes insipidus.<sup>32</sup> Hyperkalemia is secondary to drugs like trimethoprim, foscarnet, and pentamidine used in the treatment of infectious pathogens.<sup>33</sup> The combination of hyperkalemia and hyponatremia occurs due to adrenal insufficiency or hyporeninemic hypoaldosteronism.<sup>34</sup> CMV has been reported to cause central diabetes insipidus by direct involvement of the AVP-producing neurons of the hypothalamus.<sup>35</sup>

## HIV-Associated Lipodystrophy

With antiretroviral therapy increased incidence of adverse effects including metabolic changes and pseudo-Cushing phenotype are observed. Lipodystrophy (LD) is a term used to describe these changes and it includes hyperlipidemia, insulin resistance, hyperglycemia, and characteristic phenotypic changes. There is loss of peripheral fat, resulting in characteristic facial appearance of sunken cheeks and thinning of extremities. Deposition of excess adipose tissue is seen around the neck, over the dorsocervical region resulting in buffalo hump, upper torso with supraclavicular hump, and infra-abdominal region simulating Cushing syndrome. In males, gynecomastia may be seen. Acanthosis nigricans is typically not seen and there is no significant weight loss or

opportunistic infection. These patients usually have relatively high blood CD4 counts with a lower level of viremia.<sup>36</sup>

There is no uniform agreement regarding the prevalence of LD in patients on HAART because of the differences in methodology and definition of LD. Different drug combinations further compound the problem with the result that prevalence has been reported to range from 10–80%. The usual time period for the onset of dyslipidemia and hyperinsulinemia or diabetes is weeks to months. Lipodystrophy manifests 10–18 months after initiation of drug therapy.<sup>37</sup> The frequency of LD varies with the drugs used. Nucleoside reverse transcriptase inhibitors (NRTIs), zidovudine and stavudine, have been associated with morphologic changes, especially extremity fat loss, while protease inhibitors (PIs) have been associated with insulin resistance or diabetes and dyslipidemia.<sup>38,39</sup> NRTIs such as stavudine have also been associated with dyslipidemia. Since the drugs are often used together as part of HAART, clinical data suggest that they act synergistically in causing LD. The body changes are distressing and the metabolic effects have been associated with an increased risk of cardiovascular disease.<sup>40</sup>

## Insulin Resistance and Diabetes

There is higher prevalence of type 2 diabetes in the HIV infected population without lipoatrophy or wasting when compared to an HIV seronegative cohort independent of HAART. The prevalence in patients on HAART is even higher. A cohort study reported an incidence of 7% of new-onset of diabetes based on 2-hour blood glucose >200 mg/dL after oral glucose tolerance test (OGTT).<sup>41</sup> Another recent study found the incidence of diabetes to be 4 times greater in HIV-infected men when compared to HIV-seronegative men.<sup>42</sup> Mulligan et al. found a direct role for PIs in causing insulin resistance (IR) and type 2 diabetes when HIV infected patients were initiated on PI-based HAART.<sup>43</sup> The association of PI-based therapy with IR and diabetes is well-established.<sup>44</sup> Nelfinavir and atazanavir are least associated with insulin resistance.

PIs are postulated to cause insulin resistance by inhibition of glucose transporter, GLUT-4.<sup>45</sup> These drugs vary in their ability to inhibit GLUT-4 with atazanavir showing no inhibition.<sup>46</sup> PIs also impair  $\beta$ -cell function and decrease first-phase insulin release.<sup>47</sup> Other contributing factors include increased lipolysis, induction of IL-6 and TNF- $\alpha$ , and reduction in gene expression and secretion of adiponectin.<sup>48,49</sup>

Patients with lipoatrophy have pronounced mitochondrial depletion as seen in biopsies from subcutaneous lipoatrophic tissues. Mitochondrial toxicity occurs through inhibition of mitochondrial DNA polymerase- $\gamma$  leading to lactic acidosis and organ toxicities including pancreas, liver, and muscle.<sup>50</sup> Fleischman et al. have shown that stavudine reduces insulin sensitivity with concomitant mitochondrial dysfunction in healthy volunteers.<sup>51</sup> A large prospective observational study of HIV-infected patients found that stavudine and zidovudine are significantly associated with diabetes after correction for lipids and risk factors for diabetes.<sup>52</sup> Among the NRTIs, tenofovir and lamivudine have

minimal effects on mitochondrial toxicity. Drug combinations in differing HAART regimens may act synergistically to cause mitochondrial toxicity.<sup>53</sup> The differences among drugs within the NRTI in causing mitochondrial dysfunction may probably be related to the varying affinities of the drugs for the mtDNA polymerase- $\gamma$ .

## Dyslipidemia

HIV-infected patients with or without AIDS prior to the HAART era have been reported to have lipoprotein abnormalities due to the acute phase response and inflammatory mediators. Early stage of HIV infection is usually associated with lower low density lipoprotein (LDL-C) and high density lipoprotein (HDL-C) levels. With advanced HIV and AIDS, triglycerides (TGL) levels are higher and LDL particles become smaller in density and more atherogenic.<sup>54</sup> With initiation of HAART, increases in total lipoprotein and LDL-C are observed. PIs are particularly associated with significant increase in TGL, total lipoprotein, and LDL-C levels. Elevation in TGL and total cholesterol are highest with ritonavir, lower with indinavir, nelfinavir, and amprenavir and lowest with saquinavir. HDL-C is usually lowered with PIs, with nelfinavir showing the least effect. Atazanvir, a new PI has been shown to have little effect on lipids.<sup>55</sup>

PIs cause direct inhibition of glucose uptake in adipocytes resulting in a significant reduction in TGL synthesis. This leads to adipocyte shrinkage and lipoatrophy. Sterol regulatory element binding proteins (SREBPs) which function as lipid sensors are activated and transported from endoplasmic reticulum (ER) to the nucleus where they promote synthesis of cholesterol and fatty acid biogenesis.<sup>56</sup> This results in excessive accumulation of intracellular cholesterol in ER inducing the ER stress response and accumulation of unfolded proteins which promote apoptotic cell death.<sup>57</sup>

HIV associated lipodystrophy increases the risk of cardiovascular disease as a result of dyslipidemia, insulin resistance, and diabetes mellitus. The clinical utility of metformin and the thiazolidinediones, rosiglitazone, and pioglitazone in treating HIV associated lipodystrophy patients is under investigation in terms of their effect on improving insulin sensitivity and reducing the progression from impaired glucose tolerance (IGT) to diabetes in non-HIV populations.<sup>58,59</sup> The first quantitative meta-analysis of randomized controlled trials evaluating the effects of rosiglitazone, pioglitazone or metformin on insulin, glucose, lipids, and body fat redistribution in patients with evidence of lipodystrophy has delivered mixed results of each of the insulin-sensitizing drugs. Rosiglitazone improved fasting insulin levels, but adversely affects fasting lipid levels and has no effect on central adiposity. Pioglitazone does not have any favorable effect on fasting insulin, plasma glucose, and central adiposity but improved HDL-cholesterol. Metformin had favorable outcomes in reducing fasting insulin, fasting TGL, and also in reducing central obesity. Adverse effects like lactic acidosis are not reported.<sup>60</sup> Currently, it seems metformin is the

insulin-sensitizer of choice which demonstrates beneficial effects on all three components of lipodystrophy.

## Conclusions

Subclinical adrenal insufficiency is common in HIV infection. In the advanced stages adrenal insufficiency occurs due to primary involvement of the gland or secondary to infections, drugs, and tumors. Lower basal cortisol and dehydroepiandrosterone levels are seen in the HIV infected. Shift to TH2 immunologic response; peripheral cortisol resistance, and drugs like protease inhibitors are the major contributing factors. Hypogonadotrophic hypogonadism as assessed by measuring free testosterone is seen in 20–50% of HIV-infected individuals. Alterations in thyroid function with raised TBG levels and low or raised free T4 can be seen. Subclinical hypothyroidism is common in HIV-infected individuals while Grave disease may occur during immune reconstitution syndrome. Low bone mineral density is seen frequently in HIV infected individuals due to various factors. Effects of antiviral agents is controversial. Most important electrolyte imbalance seen is hyponatremia, while potassium related complications are usually secondary to drugs.

HIV-associated lipodystrophy is observed in approximately 40–50% of ambulatory HIV-infected patients. The prevalence of insulin resistance and diabetes mellitus is increasing in HIV-infected patients with LD syndrome as the longevity is prolonged with effective drugs. The management of HIV/HAART-induced LD is complicated by the fact that almost all drugs have unacceptable adverse effects. Metformin with all its beneficial role in lipodystrophy has also been shown to result in peripheral fat loss, which can be cosmetically disfiguring.<sup>61</sup> Hence, the complexity of HAART coupled with limited studies on effective therapies, and significant potential for drug interactions necessitates large, well-controlled studies for better management of lipodystrophy and other metabolic complications.

# AIDS Associated Malignancies and Their Treatment

Mark Bower • David Shackleton • Justin Stebbing

# 80

## Introduction

Acquired immunodeficiency syndrome (AIDS) following infection with human immunodeficiency virus (HIV), was brought to the world's attention in 1981 with the first case reports of *Pneumocystis carinii* pneumonia in homosexual men in Los Angeles.<sup>1</sup> These reports were quickly followed by descriptions of Kaposi sarcoma in similar patient groups.<sup>2,3</sup> There followed a cornucopia of opportunistic infections and isolated reports of high-grade B-cell non-Hodgkin lymphomas (NHL), both primary cerebral lymphomas and systemic NHL. By 1985 high-grade B cell NHL was included along with Kaposi sarcoma as an AIDS defining illness by the Centre for Disease Control (CDC) following the publication of series of 90 homosexual men with NHL.<sup>4-8</sup> A final AIDS defining malignancy, invasive cervical cancer was added as an AIDS defining illness in 1993, although the incidence of this malignancy is not increased as dramatically in HIV seropositive women.<sup>9</sup>

A number of other cancers occur at an increased frequency in people with HIV infection including Hodgkin disease, anal cancer, lung cancer, and testicular seminoma.<sup>10</sup> However, these malignancies have not been included in the definition of AIDS and they fall outside the scope of this chapter.

Dramatic improvements in the antiviral therapy of HIV infection occurred in the second half of the 1990s that have altered the natural history of HIV infection in those economies where these medicines are widely available. The introduction of highly active antiretroviral therapy (HAART) has led to a fall in the incidence of both opportunistic infection and AIDS associated malignancies.

## Highly Active Antiretroviral Therapy (HAART)

The development of effective antiretroviral therapies commenced with the introduction of nucleoside reverse transcriptase inhibitors starting with zidovudine in 1987. In the last decade, five new classes of antiretroviral agents have been introduced: protease inhibitors (e.g., saquinavir, indinavir, ritonavir, nelfinavir, lopinavir, atazanavir), non-nucleoside reverse transcriptase

inhibitors (nevirapine, delavirdine, efavirenz), non-nucleotide reverse transcriptase inhibitors (notably tenofovir), integrase inhibitors (raltegravir), and fusion inhibitors (enfuvirtide). The introduction of the first two classes in the late 1990s led to the use of combination HAART. HAART has had an enormous impact on the treatment of HIV in terms of overall survival, incidence of opportunistic infections, and quality of life. In randomized studies HAART leads to a dramatic decline in the mortality and morbidity of HIV.<sup>11</sup> However, only 1.5 million of the estimated 42 million people infected with HIV worldwide are receiving HAART as the majority of affected people live in developing countries.<sup>12</sup> In addition, even in the established market economies with access to medical treatment many individuals remain undiagnosed and consequently do not receive HAART. For the commonest AIDS-defining malignancy, Kaposi sarcoma, HAART remains an effective therapy<sup>13</sup> though its effect on lymphoma has been more controversial.<sup>14,15</sup>

## AIDS RELATED SYSTEMIC LYMPHOMA

### Epidemiology of AIDS Related Lymphoma in the Era of HAART

Non-Hodgkin lymphomas are associated with both congenital and iatrogenic immunosuppression and so it was perhaps not surprising that an increased incidence was demonstrated early in the AIDS epidemic. Registry linkage studies in the pre-HAART era found that the incidence of NHL in HIV positive individuals was 60–200 times higher than in the matched HIV negative population<sup>16,17</sup> and the relative risk was even greater for primary cerebral lymphomas.<sup>18</sup> Following the introduction of HAART the incidence of both Kaposi sarcoma and primary cerebral lymphoma has fallen significantly in both registry linkage and cohort studies,<sup>19-21</sup> this is thought to be secondary to the immune reconstitution that occurs with HAART.<sup>22,23</sup>

In contrast, the effects of HAART on systemic NHL are less clear<sup>24,25</sup> although some cohort studies suggest a modest nonsignificant decline in the incidence<sup>26</sup> including in the hemophilia population.<sup>27</sup> An international meta-analysis of 20

cohort studies compared the incidence of systemic NHL between 1992–6 and 1997–9. This meta-analysis confirmed an overall reduction in the incidence of both primary cerebral lymphoma (rate ratio = 0.42) and systemic immunoblastic lymphoma (rate ratio = 0.57) but not Burkitt lymphoma (rate ratio = 1.18).<sup>24</sup>

### Predictors of AIDS Related Lymphoma

Genetic, infectious, and immunological factors influence the development of AIDS related lymphoma. For example, germ line chemokine and chemokine receptor gene variants have been found to influence the chance of developing these tumors. Aciclovir has mild activity against Epstein–Barr *in vivo* and one case-control study has shown that administration of high-dose acyclovir ( $\geq 800$  mg/d) for  $\geq 1$  year was associated with a significant reduction in the incidence of NHL.<sup>28</sup> However, data concerning the association between serum Epstein–Barr viral DNA loads and lymphoma development are controversial.<sup>29,30</sup>

In 2000, an analysis of our cohort of 7840 HIV positive patients, identified three factors in multivariate analysis that are significantly associated with the development of systemic NHL; age, nadir CD4 cell count, and no prior HAART. As the CD4 count falls, the development of lymphoma becomes more likely.<sup>14</sup> This may explain the declining incidence of NHL since the introduction of HAART as it is thought that the immune restoration that accompanies HAART protects against the development of AIDS related lymphoma.

These data were updated in 2004 using 9621 HIV-1 infected patients in our cohort. Here, it was again found that the use of HAART protected against NHL development. Moreover, nonnucleoside reverse transcriptase inhibitor (NNRTI)-based HAART (adjusted rate ratio, 0.4; 95% CI, 0.3–0.5) was as protective as protease inhibitor (PI)-based HAART, and these were significantly more protective than nucleoside analogs alone (rate ratio, 0.5; 95% CI, 0.4–0.7) or no antiretrovirals (Fig. 80.1;  $P < 0.001$ ).<sup>26</sup>

### Clinical Presentation of AIDS Related Lymphoma

The majority of patients with systemic AIDS related lymphomas present with advanced stage disease and B symptoms. Extranodal

**Fig. 80.1:** The probability of NHL and baseline exposure to different antiretroviral drugs over 7 years. ARV, antiretroviral therapy; NA, nucleoside analogue; NNRTI, non-nucleoside reverse transcriptase inhibitor; PI, protease inhibitor.

disease, bone marrow involvement, and leptomeningeal disease are all common features. Hepatic involvement occurs in up to 25% patients while one in five patients has bone marrow involvement by NHL.<sup>8</sup> In addition, HIV infection itself is associated with trilineage abnormalities of hematopoiesis and the poor hematological reserves add to the myelotoxicity of cytotoxic chemotherapy.<sup>31,32</sup> Central nervous system involvement by systemic AIDS associated NHL is frequent; leptomeningeal disease is present at diagnosis in 3–10% and is significantly associated with Burkitt lymphoma and both bone marrow and paraspinal or paranasal involvement,<sup>33–35</sup> all of which necessitate intrathecal treatment.

In the published series from our institution that compared the clinical characteristics of 99 AIDS related lymphomas presenting prior to 1996 and 55 that presented between 1996 and 1999, there were no differences in the stage at presentation, presence of B symptoms, bone marrow infiltration, or performance status between the two groups. However, the patients who developed lymphoma in the HAART era were less likely to have had a prior AIDS diagnosis, were older, and had higher CD4 cell counts at the time of lymphoma diagnosis.<sup>14</sup> Thus although there has been a change in the immunological parameters of lymphoma patients, this would seem to reflect changes in the population at risk rather than any alteration of the biology of the lymphomas. A further analysis of patients who presented with lymphoma in the era of HAART compared those who were receiving HAART at the time of lymphoma diagnosis ( $n = 17$ ) with those who were not ( $n = 34$ ). Again there were no significant differences between the stages or disease sites at presentation but the CD4 cell counts at lymphoma diagnosis were higher in those on HAART.

### Treatment of AIDS Related Lymphoma in the Era of HAART

During the 1980s, conventional chemotherapy schedules were used at full dosages for patients with better prognostic factors. However, marked toxicity and an increased incidence of opportunistic infections lead to modifications of the standard lymphoma regimens. The subsequent development of hematopoietic growth factors allowed more myelotoxic schedules to be studied. The appreciable death rate from opportunistic infections generally offset any decline in NHL related deaths and most centers persisted with either dose reduced chemotherapy schedules or prognostic stratification that reserved full dose therapy for patients with the best prognostic factors only.<sup>36</sup>

Recently, a number of groups have described an improvement in the overall survival compared to historical controls since the introduction of HAART. The complete remission rate and overall survival with CHOP chemotherapy has improved with the addition of HAART to the chemotherapy<sup>36,37</sup> and the goal of therapy is clearly complete remission, not palliation.<sup>38</sup> However, in other series there has been no change in the lymphoma response rates and the improvements in survival duration may be related to reduced deaths from opportunistic infections among patients who achieve durable tumor remissions.<sup>39–41</sup> Nonetheless these

encouraging findings have lead to a more aggressive approach to the management of AIDS associated NHL.

Infusional chemotherapy for high-grade lymphoma was pioneered at the Albert Einstein Cancer Centre in New York using the combination of cyclophosphamide, doxorubicin, and etoposide (CDE) administered as a 96 hour continuous infusion together with granulocyte colony stimulating factor (G-CSF).<sup>42</sup> Early reports of a selected group of 25 patients with AIDS related lymphomas who were treated with CDE and didanosine produced an impressive median survival of 18.4 months and was widely heralded as a breakthrough.<sup>43</sup> The same schedule was then combined with saquinavir, with similar results although there was more mucositis with the protease inhibitor. A large multicenter phase II trial of infusional CDE has been conducted by the Eastern Cooperative Oncology Group and the results have been far less impressive as is so often the case following encouraging initial single center studies.<sup>44</sup>

In our cohort, 56 patients with systemic AIDS-related non-Hodgkin lymphoma (ARL) were treated with concomitant HAART and infusional CDE chemotherapy. We compared neutropenia according to whether patients received protease inhibitor PI-based HAART or non-PI regimens. Differences in survival, response rates, immunologic parameters, and virologic parameters were also investigated. The day-10 (Mann-Whitney U test;  $P = 0.012$ ) and day-14 ( $P = 0.025$ ) neutrophil counts were significantly lower in patients receiving PIs, though there were no differences in the number of days of granulocyte colony-stimulating factor (G-CSF) administered between groups ( $P = 0.16$ ). Grade 3 or 4 infections requiring hospitalization were recorded for a total of 58 (31%) of 190 cycles of CDE: 23 (48%) of 48 when prescribed PIs and 35 (25%) of 142 with concomitant PI-sparing HAART ( $P = 0.0025$ ). There were no statistically significant differences in the response rates, relapse-free survival, or disease-free survival between patients receiving PIs and those not receiving PIs. PI-based HAART appears to significantly potentiate the myelotoxicity of CDE chemotherapy.<sup>45</sup>

At the National Cancer Institute, EPOCH (etoposide, prednisolone, vincristine, cyclophosphamide, doxorubicin), a dose-adjusted schedule has been developed which omits all HAART for the duration of the chemotherapy. Initial reports have been encouraging with a complete response rate of 79%. However, there was a dramatic fall in CD4 cell count during chemotherapy and even with restarting the HAART at the end of the chemotherapy; this took 12 months to recover to baseline levels.<sup>46</sup> This phase II study has been expanded to 39 selected patients now<sup>47</sup> and EPOCH is currently under investigation in a multicenter study. As there are no comparative studies, it is difficult to recommend an optimal gold standard therapy and there are advocates of conventional CHOP as well as supporters of infusional therapies.

The high rate of leptomeningeal disease at presentation, which may be asymptomatic led to the widespread use of staging lumbar punctures and prophylactic intrathecal chemotherapy for patients

considered to be at high risk of relapse in the cerebrospinal fluid. The prophylactic administration of intrathecal chemotherapy to patients with these risk factors but without meningeal disease at presentation prevented meningeal relapse in 81%.<sup>48</sup>

Chemotherapy results in a decline in CD4 cell counts in both the immunocompetent and immunocompromised and prophylaxis to prevent opportunistic infections particularly in this patient group requires careful attention. It is well-established in the management of HIV infection that prophylaxis against *Pneumocystis carinii* pneumonia should commence when the CD4 cell count falls below 200/mm<sup>3</sup> and against *Mycobacterium avium* complex when it falls below 50/mm<sup>3</sup>.<sup>49,50</sup>

The prolonged T cell depletion recorded following EPOCH was previously demonstrated for patients receiving chemotherapy in the pre-HAART era.<sup>51</sup> The concomitant use of chemotherapy and HAART has been widely practiced and when used together the CD4 cell count declines by 50% during chemotherapy but recovers rapidly within 1 month of completing chemotherapy. The CD8 and natural killer (CD16 and CD56) cell counts follow a similar profile while the B cell (CD19) count recovers more slowly but is restored to prechemotherapy levels by 3 months. There was no change in the HIV mRNA viral load during the chemotherapy.<sup>52</sup> In view of the decline in CD4 cell count by 50%, PCP prophylaxis should commence at CD4 cell counts of 400/mm<sup>3</sup> and MAC at CD4 counts of 100/mm<sup>3</sup>.

The improved survival described since the introduction of HAART and the preservation of immune function suggests that the combination of chemotherapy with HAART is an important step forward in the management of AIDS related lymphomas. However, there are both toxicity and pharmacokinetic drawbacks to the concomitant administration of chemotherapy and HAART. For example, the potentiation of myelotoxicity with CDE combined with protease inhibitors may be a consequence of microsomal enzyme inhibition reducing the metabolism of cytotoxics in this regimen.<sup>45</sup>

## Outcomes in the Era of HAART

The complete remission rates for regimens using the combination of chemotherapy and HAART are 48–92% and the published 2 year overall survivals are 48–60%.<sup>53–58</sup> These response rates and survival duration statistics are starting to approach those seen in the general population with advanced stage high-grade lymphoma. Indeed while the prognostic factors for survival in the pre-HAART era were predominantly immunological (prior AIDS defining illness and CD4 cell count) a more recent analysis of prognostic factors in AIDS related lymphoma closely resembles that for the general population with the international prognostic index being an equally valuable guide in both circumstances.<sup>59</sup> Recent data from our institution suggests the CD4 count to be an independent prognostic variable too, and a prognostic model has been established based solely on international prognostic index (IPI) scores and CD4 cell counts.

## Future Developments for AIDS Related Lymphomas

The improvements in the treatment of HIV infection have led to a more aggressive management strategy for AIDS related lymphomas and this has resulted in better outcomes. Further refinements mirror those seen in immunocompetent patients with high-grade lymphoma including the addition of anti-CD20 antibodies to first-line therapy and the use of high-dose chemotherapy with autologous stem cell transplantation at first relapse. Rituximab in addition to chemotherapy has yielded increased response rates (70% complete response with a 59% 2 year survival).<sup>36</sup> Patients have also undergone successful autologous stem cell transplantation for AIDS related lymphomas despite predictions that adequate harvesting would prove difficult on account of myelodysplasia.<sup>60–63</sup>

## PRIMARY CEREBRAL LYMPHOMA

Primary central nervous system lymphoma (PCL) is defined as non-Hodgkin lymphoma that is confined to the craniospinal axis without systemic involvement. This diagnosis is rare in immunocompetent patients but occurs more frequently in patients with both congenital and acquired immunodeficiency. AIDS related PCL occurs equally frequently across all ages and transmission risk groups and the tumors are high-grade B-cell diffuse large cell or immunoblastic non-Hodgkin lymphomas. The presence of Epstein–Barr virus is a universal feature of HIV-associated PCL but EBV is not found in other PCL.<sup>64</sup> EBV may be detected by immunocytochemical staining of biopsy tissue or by polymerase chain reaction (PCR) amplification of cerebrospinal fluid (CSF) using EBV specific oligonucleotide primers.<sup>65,66</sup>

## Epidemiology

Registry linkage studies confirmed a markedly increased relative risk of PCL among patients with AIDS with an incidence as high as 2–6% in one early report.<sup>67</sup> This vastly elevated incidence of PCL was confirmed by both cohort and linkage studies. Patients who developed PCL generally have advanced immunosuppression and for the most part have had a prior AIDS defining illness. Shortly after the introduction of HAART a decline in the incidence of PCL was recognized by many clinicians and a meta-analysis of cohort studies that compare the pre and post HAART eras confirmed a significant decline (relative risk 0.42: 99% confidence interval 0.24–0.75).<sup>24</sup> Indeed this fall is more dramatic than that seen for systemic AIDS related lymphomas and PCL is associated with more severe immunosuppression than systemic AIDS related lymphoma.

## Clinical Presentation and Differential Diagnosis

The commonest causes of cerebral mass lesions in HIV seropositive patients are toxoplasmosis and primary cerebral lymphoma and the differential diagnosis often proves difficult.<sup>68</sup> Both diagnoses

occur in patients with advanced immunodeficiency (CD4 cell counts  $< 50 \times 10^6/L$ ) and present with headaches and focal neurological deficits. Clinical features that favor PCL include a more gradual onset over 2–8 weeks and the absence of a fever. CT and MRI scanning usually reveal solitary or multiple ring enhancing lesions with prominent mass effect and edema. Again these features occur in both diagnoses although PCL lesions are usually periventricular while toxoplasmosis more often affects the basal ganglia. Thus, the combination of clinical findings and standard radiological investigations rarely provide a definitive diagnosis. Moreover, toxoplasma serology (IgG) is falsely negative in 10–15% of patients with cerebral toxoplasmosis. More than 85% patients with cerebral toxoplasmosis will respond clinically and radiologically to 2 weeks of antitoxoplasma therapy and this has become the cornerstone of the diagnostic algorithm for cerebral masses in severely immunodeficient patients.

In these patients it has been standard practice to commence empirical antitoxoplasmosis treatment for 2 weeks duration, and resort to a brain biopsy if there is no clinical or radiological improvement. This strategy avoids the routine use of brain biopsy in these patients who frequently have a very poor performance status and prognosis. Although this algorithm avoids early surgical intervention, it is relatively ineffective in diagnosing PCL early, and may compromise the outcome of therapy in these patients. In addition, there is a disinclination to treat patients with radiotherapy or chemotherapy empirically based exclusively on the failure of antitoxoplasmosis treatment without a definitive histological diagnosis.

The discovery that all HIV-associated PCL are associated with EBV infection has led to the development of a PCR method that can detect EBV-DNA in the CSF. This has become established as a diagnostic test with a high sensitivity (83–100%) and specificity ( $>90\%$ ).<sup>69,70</sup> In addition, radionuclide imaging by <sup>201</sup>Thallium single photon emission computed tomography (<sup>201</sup>Th-SPECT) or <sup>18</sup>Ffluorodeoxyglucose-positron emission tomography (FDG-PET) is able to differentiate between PCL and cerebral toxoplasmosis. PCL are thallium avid and demonstrate increased FDG uptake on PET scanning, however although both techniques have high specificity for PCL neither are highly sensitivity and thus cannot be used alone but in combination with PCR are emerging as a diagnostic alternative to brain biopsy. The application of PCR and <sup>201</sup>Th-SPECT in the diagnosis of contrast enhancing brain lesions in 27 patients was shown to result in a positive and a negative predictive value of 100% and 88%, respectively, which supports their combined value as an alternative to brain biopsy.<sup>71</sup> Further studies are now required to compare effectiveness of PCR with <sup>201</sup>Th-SPECT or FDG-PET.

## Treatment

The standard treatment modality of PCL is whole brain irradiation but the median survival time is just 2.5 months or less. Although patients who were treated with radiotherapy or chemotherapy

lived longer than those who received best supportive care only, no randomized studies have been conducted and it remains uncertain whether therapy improves survival.<sup>72</sup> There is increasing enthusiasm for the treatment of PCL in immunocompetent patients with both radiotherapy and chemotherapy and recent results have been encouraging. The use of chemotherapy for PCL is limited by the poor penetration of cytotoxics into brain parenchyma on account of the blood brain barrier and the toxicity especially myelosuppression of these agents in patients with advanced immunosuppression and poor performance status. Combination chemotherapy prolongs survival in immunocompetent patients with PCL but at the cost of severe myelotoxicity. Single agent chemotherapy with intravenous high-dose methotrexate and folinic acid rescue was studied in AIDS patients with PCL in the context of a prospective uncontrolled study which included 15 patients. The results showed a complete response in 47% of patients, a median survival of 19 months; a low relapse rate of approximately 14% and no evidence of neurological impairment nor treatment limiting myelotoxicity.<sup>73</sup> A controlled trial of intravenous methotrexate versus whole brain irradiation is needed to confirm these encouraging results. Now that antiretroviral therapies are improving survival it may be necessary to reassess currently available diagnostic and treatment modalities aiming to cure HIV-associated PCL.

One intriguing development is the description of tumor regression of PCL with HAART therapy alone.<sup>74</sup> These case report observations require confirmation in cohort studies but in our experience very few patients with HIV-associated PCL are HAART naïve at the time of diagnosis of PCL.

## KAPOSI SARCOMA (KS)

### Epidemiology, Virology, and Pathogenesis

Soon after the first events of the HIV epidemic, the New York Times headline “Rare cancer seen in 41 homosexuals” referred to cases of KS. This aggressive and frequently fatal epidemic variant of KS affected homosexual men with AIDS approximately 20 times as frequently as male patients with hemophilia and AIDS who had similar degrees of immunosuppression.<sup>75–79</sup> Although the incidence of KS in American men with AIDS decreased from 40% in 1981 to less than 20% in 1992, today it remains the most common AIDS-associated cancer in the United States and an important cause of morbidity and mortality, particularly in sub-Saharan Africa.<sup>80–87</sup>

While a total of four clinical variants of KS have now been described, known as classical, endemic, iatrogenic (post-transplant), and epidemic (AIDS-associated) forms,<sup>88</sup> in the light of recent discoveries regarding the viral pathogenesis of KS, these variants are thought to represent different manifestations of the same pathologic process.<sup>89</sup>

It was noted early in the HIV pandemic that AIDS associated KS was more prevalent in gay men than in other transmission groups and this observation led Valerie Beral and Harold Jaffe to propose that a second infectious agent could account for the

prevalence of KS in immunodeficient patients.<sup>77,90</sup> In 1994 Chang and colleagues used representational difference analysis to identify DNA fragments of a previously unrecognized herpesvirus, which they called Kaposi sarcoma-associated herpesvirus (KSHV), also known as human herpesvirus-8).<sup>91</sup> This was the second oncogenic virus after human papillomavirus, to be identified by molecular techniques. Soon after, KSHV was implicated in the etiopathology of primary effusion lymphoma (PEL)<sup>92</sup> and multicentric Castleman disease (MCD),<sup>93,94</sup> the management of which will be discussed later. Although studies have been published on the contribution of cytokines as well as HIV-1 Tat protein in the pathogenesis of KS, the presence of KSHV is a necessary factor in the development of this tumor and it can be found in every KS lesion, at every stage of its development. In addition, immunosuppression in the host appears to be an important cofactor in the clinical expression of KS in KSHV-infected individuals.<sup>95</sup>

The 165 Kb KSHV genome was sequenced within 2 years of the virus’ discovery and it provided initial clues about the way in which this virus might induce uncontrolled cellular proliferation.<sup>96</sup> Unusual to KSHV (among the herpes viruses) and its newly discovered primate cousins is the very large number of genes encoding homologs of host genes.<sup>97–105</sup> For example, KSHV encodes a homolog of cyclin D2 whereas the related gamma-herpesvirus EBV LMP-1 induces cyclin D2 in B-cells (which normally do not express this protein).<sup>106</sup> It is thought that the acquisition of host genes may enable KSHV to utilize many host cellular processes and avoid antiviral responses. The virus encodes proteins that are homologous to human oncoproteins, including another cyclin that inhibits the retinoblastoma protein, which controls the G1-to-S phase of cell growth, and a Bcl-2-like protein that prevents apoptosis.<sup>107–110</sup>

KSHV also encodes a viral homolog of interleukin-6 (vIL-6), which is thought to act in a paracrine manner and stimulate a local acute phase response. Increased levels of IL-6 are found in tissues affected by KSHV and IL-6 is thought to be an important growth factor in not only KSHV driven neoplasms<sup>111–114</sup> but also in lymphomas driven by Epstein–Barr virus.<sup>115,116</sup> As such, there are data that suggest that KS is not a clonal neoplasm per se but begins as a localized inflammatory response.<sup>117</sup>

### Clinical Features

The first cases of KS described in 1872 were observed to be “idiopathic pigmented multiple sarcomas of the skin”.<sup>118</sup> AIDS related KS exhibits a wide spectrum of clinical presentations and some patients may have few lesions, others many—these sometimes develop rapidly.<sup>82</sup> The earliest cutaneous lesions are frequently asymptomatic innocuous looking macular-pigmented lesions, which vary in color from faint pink to vivid purple. Larger plaques occur usually on the trunk as oblong lesions following the line of skin creases. Lesions may develop to form large plaques and nodules that can be associated with painful edema. Lymphatic infiltration is a common feature in the limbs and causes lymphedema and ulceration.

Oral lesions are a frequent accompaniment that may lead to ulceration, dysphagia, and secondary infection while gastrointestinal lesions are usually asymptomatic but may bleed or cause obstruction. Pulmonary KS is a life threatening complication that usually presents with dyspnea and a dry cough with or without fever and may cause hemoptysis. Chest radiographs typically reveal a diffuse reticulonodular infiltrate and pleural effusion. The main differential diagnosis of cutaneous KS is bacillary angiomatosis, a feline zoonosis caused by *Bartonella henselae*, a fastidious gram-negative bacterium of the Rickettsia family.<sup>119–121</sup>

## Treatment of KS

The prognosis of patients with KS depends upon both the stage of the KS, the level of immunosuppression, and the response to anti-HIV therapy.<sup>122</sup> KS is staged using the AIDS clinical trials group modified staging classification (see Table 80.1). For patients with symptomatic disease or life threatening visceral disease prompt effective therapy is usually merited, while for patients with asymptomatic indolent lesions HAART alone may result in complete regression.

## Highly Active Antiretroviral Therapy

Current data suggests that there has been a fall in the incidence of KS both as a first AIDS diagnosis and a subsequent manifestation in HIV seropositive cohorts from established market economies. This decline in KS coincides with the introduction of HAART and in some cohort studies the relative risk of developing KS is significantly lower among people receiving HAART regimens.<sup>21,25,124–126</sup> A large number of case reports and small studies documenting responses of KS to HAART have been published and regression of KS during monotherapy with zidovudine has also been observed.<sup>127</sup>

A cohort study of 78 patients with established KS has demonstrated that the introduction of HAART therapy is associated with a prolongation of the time to treatment failure of KS (log rank  $\chi^2=16.5$ ,  $P < 0.0001$ ).<sup>128</sup> Thus HAART therapy has a major influence both on the epidemiology and clinical progression of KS without apparently having a direct effect upon the causative herpesvirus, KSHV. The lower incidence and regression of KS observed with HAART may result from a

variety of effects but is likely to include immune reconstitution following HAART with increased natural killer and cytotoxic T lymphocyte activity.<sup>129</sup>

As protease inhibitors have been suggested in some studies to have specific antiangiogenic and thus anticancer activity,<sup>130</sup> we compared antiretrovirals to determine whether their anti-KS effects were largely confined to PIs. Multivariate logistic regression analyses of 1204 cases of AIDS-KS seen between 1986 and 2002, found that the incidence decreased from 30 cases per thousand patient years (PY) prior to 1995 to 7.6 immediately thereafter. This was clearly coincident with treatment using dual nucleoside analog reverse transcriptase inhibitors. More recently the incidence has fallen dramatically to 0.03 cases per thousand patient years, although to our surprise patients receiving non-PI based therapies had a statistically significant difference in their incidence of KS when compared with those treated with PIs: 0.2 cases per 1000 patient years (95% CI 0.02–0.12) versus 1.1 cases per 1000 patient years (95% CI 0.15–0.38), respectively, ( $P = 0.002$ ).<sup>21</sup> This study, the first showing a decreased incidence of an AIDS defining illness with NNRTI based therapy, demonstrates that non-PI based regimens are at least as effective as PI-based HAART in terms of protection against KS (Fig. 80.2).

We have also found lack of correlation with angiogenic markers as measured by ELISA to response and overall these data further implicate the immune system in tumorigenesis.<sup>131</sup> As many cases of KS do not resolve with HAART alone or are considered 'too aggressive' for HAART, cytotoxic chemotherapy is often used to induce responses.

A proportion of individuals with human immunodeficiency virus infection (HIV) who subsequently receive HAART

**Table 80.1:** The Modified AIDS Clinical Trials Group Staging of KS (1997)<sup>123</sup>

	Good risk (all of the following) T0 I0	Poor risk (any of the following) T1 I1
Tumor (T)	Confined to skin, lymph nodes, or minimal oral disease	Tumor-associated edema or ulceration Extensive oral KS Gastrointestinal KS KS in other non-nodal viscera
Immune status (I)	CD4 count $>150/\mu\text{L}$	CD4 $<150/\mu\text{L}$

**Fig. 80.2:** Multivariate log linear model showing significant independent predictors of KS during the HAART era.

exhibits deterioration in their clinical status, despite control of virologic and immunologic parameters. This clinical response, known as the immune reconstitution inflammatory syndrome (IRIS) occurs secondary to an immune response against previously diagnosed pathogens. Occasional case reports of this phenomenon occurring for KS have been presented. We studied a cohort study of 150 patients with HIV-associated KS starting HAART for the first time as sole treatment for the KS. After commencing HAART, ten of these patients (6.6%) developed progressive KS which we identified as IRIS-associated KS. IRIS-KS occurred in patients with higher CD4 counts ( $P = 0.03$ ), KS associated edema ( $P = 0.01$ ) and therapy with both protease inhibitors and non nucleosides together ( $P = 0.03$ ). Time to treatment failure was similar for both groups, although the CD4 count declined more rapidly at first, in those with IRIS-associated KS. Despite this initial decline, in our clinical experience HAART could be successfully continued in those with IRIS-associated KS.<sup>132</sup>

## Chemotherapy for KS

### Liposomal Anthracyclines

Liposome encapsulation of anthracyclines constitutes a considerable advance in the chemotherapy of KS. The advantages of liposomal formulation include increased tumor uptake and hence favorable pharmacokinetics.<sup>133–138</sup> Moreover, the liposomal forms are less cardiotoxic than the parent anthracyclines. Both liposome encapsulated daunorubicin (Daunoxome 40 mg/m<sup>2</sup> every 2 weeks) and the pegylated liposomal doxorubicin (Caelyx 20 mg/m<sup>2</sup> every 3 weeks) have been shown to have good antitumor activity. The toxicity profile is better than for other anthracyclines, with no reported cardiotoxicity even with high cumulative dosages and rarely significant alopecia; however there remains considerable myelosuppression, and occasional emesis.

In addition, infusion related hypotension and hand/foot syndrome are novel side effects seen with these liposomal formulations. In randomized comparisons of liposomal doxorubicin compared to other chemotherapies as first-line therapy for KS, response rates were higher liposomal doxorubicin arm.<sup>139–141</sup> Liposomal anthracyclines are considered first-line chemotherapy for advanced KS.

### Paclitaxel

Paclitaxel has been shown to have single agent activity against KS and has a valuable role in the management of refractory disease. The toxicities of paclitaxel are well-recognized, although appear to be no worse in patients with HIV than in other groups treated with equivalent dosages. Two studies of refractory KS have shown response rates of 53% and 71% and median response durations of 7.4 and 10.4 months.<sup>142,143</sup> These results have led to the rapid acceptance of paclitaxel (100 mg/m<sup>2</sup> over 3 hours every 2 weeks) as the treatment of choice for anthracycline refractory KS.<sup>131,142</sup>

Unsurprisingly, weekly docetaxel has also been shown to be safe and effective in a small phase 2 study.<sup>144</sup>

### Other Agents and Radiotherapy

A number of other chemotherapeutic agents have demonstrated activity against Kaposi sarcoma. These include etoposide, bleomycin, and vincristine.<sup>145,146</sup> Localized therapies are advocated for patients with limited non-life threatening cutaneous disease. An intralesional injection of a dilute solution of vinblastine (0.2 mg/ml) using volumes of up to 0.5 ml per lesion is an effective, easy, and well-tolerated treatment for lesions under 1 cm in diameter. Intralesional vinblastine has no significant systemic effects and injections may be repeated 2 or 3 times. This approach is also valuable for small intraoral lesions and gingival lesions. The United States Food and Drug Administration has recently approved 0.1% 9-cis-retinoic acid gel as a topical treatment for AIDS-related KS based on one vehicle-controlled trial. Here, 35% of patients who received a 12-week course of the gel and 18% of patients treated with the vehicle gel demonstrated an objective response ( $P = 0.002$ ).<sup>147</sup> Application site reactions (i.e., erythema, bruising, flaking) were common but rarely severe.<sup>148,149</sup> Additional topical treatments available include liquid nitrogen.

Larger cutaneous or oral lesions may be treated with radiotherapy and local control is generally achieved. For cutaneous lesions either a single fraction of 8Gy or 16Gy in four fractions is routinely used. Although the response rate and duration of local control may be better with fractionated regimens compared with single fraction treatment, toxicity and patient convenience are worse. Cosmetic improvement is usually achieved although there may be a halo appearance on account of the margin around treated lesions. Severe mucositis and acute edema reactions may follow radiation treatment of the oral cavity and feet and for this reason treatment is given in four fractions at weekly intervals. Recurrent tumor is common and therefore radiotherapy treatment is usually reserved for symptomatic and cosmetically disturbing lesions.<sup>150</sup>

## Future Developments for AIDS-Related Kaposi Sarcoma

KS has been recognized as a clinical entity for well over a century and has been a known complication of HIV infection for 3 decades. It is only in the last few years since the discovery of KSHV as its causative agent that the multiplicity of factors in its pathogenesis is being unravelled. A wide variety of treatments appear able to inhibit KS growth including antiretrovirals, cytotoxic chemotherapeutic agents, retinoids, thalidomide, and inhibitors of matrix metalloproteinases. There is also considerable interest in evaluating the role of antiherpes drugs for KS. The role of interferon- $\alpha$ , both pegylated and nonpegylated forms are being established in clinical trials following significant evidence of antineoplastic and antiviral activity *in vitro*.

An improved understanding of the functions of the KSHV genes, the identification of novel immune-evasion strategies and

the analysis of the KS microenvironment in the context of a viral infection, should lead to a better understanding of angiogenesis, the immune system, and the interaction of viruses with their hosts. This will help us to design safer strategies to treat virus-induced pathology. As many cases of KS do not resolve with HAART and require treatment with cytotoxic chemotherapy, it is also important to reveal the underlying mechanisms involved in the response to treatment.

## CERVICAL CANCER

### Epidemiology

Invasive cervical cancer was included as an AIDS defining diagnosis in 1993, although the incidence of cervical cancer was not then increased significantly in HIV seropositive women.<sup>9,151</sup> Nonetheless there is good epidemiological evidence that the precursor lesions, cervical intraepithelial neoplasia (CIN) or squamous intraepithelial lesion (SIL) occur more frequently in women with HIV.<sup>152</sup> Human papillomavirus (HPV) has a central role in the pathogenesis of both CIN and invasive cervical cancer. HIV is associated not only with a higher prevalence of HPV in the cervix, a high frequency of multiple HPV genotypes and persistence of HPV in the cervix, but also a higher prevalence of CIN/SIL, a higher progression from low-grade SIL to high-grade SIL, and a greater likelihood of relapse of CIN II/III after therapy. The risk of SIL is greatest among women with CD4 cell counts <200 cells/mm<sup>3</sup>. These findings mandate close colposcopic surveillance.<sup>153</sup>

### Effects of HAART on Pre-invasive Cervical Cancer

The effect of HAART on the natural history of CIN has been addressed in women with advanced HIV. Five months after starting HAART the prevalence of CIN fell from 66% to 49%, regression of HGSIL to LGSIL occurred in 23% and from LGSIL to normal in 43%. These changes occurred without a significant change in the level of HPV DNA in cervical tissue.<sup>154</sup> In a recent women's interagency HIV study (WIHS) cohort from 5 US cities, the effect of HAART on CIN was assessed by 6 monthly smear testing. After adjustment for CD4 cell count and Papanicolaou smear status, women on HAART were 40% (95% confidence interval, 4–81%) more likely to demonstrate regression and less likely (odds ratio, 0.68; 95% confidence interval, 0.52–0.88) to demonstrate progression.<sup>155</sup> However the benefits of HAART have not been reproduced in all studies and HAART appears to have limited ability to clear HPV infection and induce regression of CIN in HIV-positive women. Current data suggest that frequent cervical smears should be offered to all HIV positive women and that CIN should be aggressively treated in these women.

### Invasive Cervical Cancer Management

In most centers HIV seropositive women with invasive cervical cancer are treated using the same protocols as immunocompetent

women. One retrospective series compared 28 HIV positive women with 132 seronegative women treated at the same institution and time period. The results demonstrated that women with HIV had more advanced cervical cancer at presentation.<sup>156</sup> A similar case control study from the same institution demonstrated that women with cervical cancer who were HIV seropositive relapsed more frequently and had a worse median survival.<sup>157</sup> Although there is hope that the survival of invasive cervical cancer may improve with the introduction of HAART, there is scant data to support this optimism.<sup>158</sup>

As HPV also causes anal intraepithelial neoplasia (AIN), the precursor lesion for anal cancer, we have examined whether effective HAART leads to regression of AIN. Results were inconclusive<sup>159</sup> although we did find in 99 men that anal cytology by the Palefsky method is simple to undertake, has a sensitivity and specificity comparable with cervical cytology, and can therefore be used as the basis of a pilot screening project in centers with large cohorts of HIV positive homosexual men who have a high risk of developing anal carcinoma.<sup>160</sup> Unlike other HIV-associated cancers, there has been no significant change in the incidence, clinical features, or overall survival since the introduction of HAART.<sup>161</sup>

### Primary Effusion Lymphoma (PEL)

PEL is an unusual lymphoproliferative disorder, accounting for 2% or less of HIV-associated lymphomas, and is even more rarely encountered in the HIV-seronegative patient. PEL is divided into classic and solid variants. Classic PEL is characterized by lymphomatous involvement of the serosal surfaces, whereas solid PEL manifests initially with tissue-based tumors and no malignant effusions.<sup>162,163</sup> They are similar by morphology, immunophenotype, and molecular analysis. KSHV along with high levels of interleukin (e.g., IL-6) may be found in PEL tumor cells and this is frequently necessary to aid in the diagnosis. The ramifications of large and typically recurrent pleural, pericardial, and peritoneal effusions are grave and are responsible for the high morbidity and mortality associated with this condition.<sup>164</sup>

PEL cells have a characteristic phenotype highlighted by CD45, CD30, CD38, CD138, and MUM1 coexpression.<sup>162</sup> Classic B-cell markers (CD19, CD20) and T-cell markers (CD2, CD3, CD5, CD7) are not typically seen. Gene expression profiling has shown that PEL expresses a gene profile distinct from other lymphomas, but more akin to multiple myeloma cell lines.

There is no clear standard of care established in the treatment of PEL, and due to its low incidence, randomized clinical trials at present are not feasible. As with the other KSHV-associated diseases, if HIV coinfection is identified, antiretroviral therapy is critical. Spontaneous regression with the commencement of HAART has been described.<sup>165</sup> Traditionally, the use of standard cytotoxic regimens used for non-Hodgkin lymphomas are suboptimal, and median survival in treated cohorts is poor. Induction of apoptosis with the inhibition of NF-κB in PEL cell

lines has led to the investigation of proteasome inhibitors which decreases the activation of NF- $\kappa$ B and its antiapoptotic effects.<sup>166</sup> Bortezomib, a proteasome inhibitor that is FDA approved in the USA for use in multiple myeloma, has been shown to enhance the *in vitro* cytotoxic effects of doxorubicin and paclitaxel, and has been used successfully in combination with anthracycline-based cytotoxic chemotherapy regimens. Inhibition of mTOR with rapamycin is effective at decreasing *in vitro* PEL growth and *in vivo* mouse xenograft model tumor growth, and its increasing use in the treatment of PEL can be foreseen.<sup>167</sup> Cases of prolonged survival in persons treated adjunctively with antiviral therapy (ganciclovir or cidofovir) have also prompted the adjunctive use of these drugs in PEL. Valproate to treat PEL induces lytic KSHV replication and leads to apoptosis in combination with antiviral agents.

### Multicentric Castleman Disease (MCD)

MCD is a rare lymphoproliferation and we have calculated that in the HAART era it has an incidence of 4.3/10,000 patient years.<sup>168</sup> MCD is an aggressive lymphoproliferative disorder, characterized by constitutional symptoms, anemia, and generalized lymphadenopathy. Small series have shown that most MCD cases are driven by KSHV, including 100% of HIV-seropositive patients and the majority of HIV-negative patients.<sup>169</sup> The failure to identify KSHV in all MCD lesions may either reflect technical limitations in KSHV detection, the ability for KSHV to induce MCD distant to the biopsied tissue, or an alternate etiology for a limited number of cases. On occasion, MCD may be associated with non-Hodgkin lymphoma, particularly the plasmablastic variant. A key to making the diagnosis is to suspect MCD in high-risk individuals who present in the appropriate clinical context (i.e., immunosuppressed individual with KSHV infection or other KSHV associated disease). Definitive diagnosis can only be made by pathologic examination of an involved lymph node or extranodal mass. Detection of KSHV in biopsied tissue or in the peripheral blood can aid in the diagnosis. C-reactive protein, KSHV viral load, and serum IL-6 levels, if available, may be useful as markers of disease activity and response to therapy.<sup>170</sup>

In patients with MCD and HIV infection, treatment with antiretroviral therapy is necessary, but caution should be taken as life-threatening flares of MCD have been reported as a manifestation of immune reconstitution. Splenectomy can be useful in establishing the diagnosis and can induce clinical remissions, however these are short-lived and relapse typically occurs within a few months. Systemic therapy is the mainstay of treatment for patients with MCD and ranges from aggressive remission-induction chemotherapy regimens [CHOP (cyclophosphamide-doxorubicin-vincristine-prednisone); ABV (doxorubicin-bleomycin-vincristine)], single agent maintenance chemotherapy (oral etoposide, cyclophosphamide, vinblastine), immunomodulatory agents (thalidomide, interferon- $\alpha$ ), and monoclonal antibodies against the IL-6 receptor (atlizumab) and CD-20 (rituximab).<sup>171</sup>

Among all of these treatments, rituximab has shown the most promise in inducing durable remissions. In a prospective study of 24 individuals with chemotherapy-dependent HIV-associated MCD, rituximab was associated with sustained remission off treatment at day 60 (the primary end point) in 22 patients (92%).<sup>66</sup> More recently, the efficacy and safety of 4 weekly infusions of rituximab in 21 consecutive patients with previously untreated plasmablastic HIV-associated MCD has been investigated.<sup>172</sup> All but one patient achieved clinical remission of symptoms, hematological and serum chemistry normalization, and 70% achieved a radiological response. In 3 patients who relapsed, retreatment with rituximab was successful.<sup>173</sup> The main adverse event seen in these patients is reactivation of KS, which is intriguing and may be due to a rapid B-cell depletion that is observed during rituximab therapy, or an IRIS to hitherto latent antigens. Rituximab therapy in this study was shown to be associated with a decline in KSHV levels initially and at the successful treatment of relapse.

Given the lytic nature of KSHV in MCD, antiviral therapy is also a consideration. A recent randomized controlled trial demonstrated the efficacy of valganciclovir in reducing KSHV replication in individuals with KSHV infection but without evidence of KS, PEL, or MCD. In patients with MCD, ganciclovir, and valganciclovir have been independently shown to induce remissions alone or in combination with other agents.<sup>174</sup>

### Conclusion

In the 1960s, the then surgeon general of the United States announced that infectious diseases would no longer be a problem. This followed the eradication of both smallpox and polio. Since the 1980s, approximately 22 million have died of AIDS often as a result of ensuing cancers which can in some ways be regarded as opportunistic infections themselves. The peak of the AIDS epidemic in the USA occurred in 1993, and by 1995 there was a decline in the incidence of new patients due to the widespread use of HAART which in resource-rich regions resulted in a 73% decrease in the development of AIDS among HIV-infected people, and an equally remarkable 75% decline in mortality among patients with AIDS. Nonetheless, the prevalence of HIV continues to increase, driven by a stable number of new infections each year and longer survival of those infected.

HAART has also been associated with dramatic decreases in the incidence of Kaposi sarcoma, and to a lesser extent, AIDS-related lymphoma. It is now clear that effective control of the underlying HIV and its related immunosuppression prevents development of these cancers. However, the vast majority of HIV-infected individuals do not have access to HAART because of financial and social circumstances. We are thus left with the stark reality that malignant disease may be preventable but only in resource-rich areas of the world.

An understanding of the pathways that EBV, KSHV, and HPV utilize to induce cellular proliferation provides us an understanding of conserved pathways in cellular evolution.

Their targeting will undoubtedly reveal new mechanisms involved in transformation and the hope is that these in turn will reveal new drug targets that will help the eradication of both HIV and cancer.

### Summary

There is a markedly increased risk of Kaposi sarcoma, non-Hodgkin lymphoma, and invasive cervical cancer during the course of infection with the human immunodeficiency virus. Therapy for these AIDS-defining illnesses first involves antiretroviral therapy to suppress HIV viremia and maintain CD4 counts. Subsequent chemotherapy is complicated by the underlying immunoparesis and options in the management of all three diseases are discussed herein. New data related to multicentric Castlemann disease represents a model for future management of rare proliferations that are observed in the setting of HIV. Improved understanding of their etiopathogenesis will hopefully delineate new therapeutic options and strategies to control viral replication and virally induced diseases including malignancy.

# Rheumatic Manifestations of HIV and AIDS

Vikram A. Londhey • Milind Y. Nadkar

## 81

### Introduction

Rheumatic manifestations can develop during the course of HIV infection at any stage of the disease but are more often seen in the late stages of the disease.<sup>1,2</sup> These musculoskeletal disorders can cause a significant morbidity in patients, thereby affecting their quality of life. The first report of Reiter syndrome in AIDS was published in 1987. Since then, a variety of musculoskeletal disorders have been described in these patients. These include non-inflammatory pain syndromes, non-specific inflammation, autoimmune diseases like vasculitis, Sjogren-like syndrome called diffuse infiltrative lymphocytosis syndrome (DILS), infectious rheumatic diseases (osteomyelitis, pyomyositis, septic arthritis), and those resulting from initiation of highly active antiretroviral therapy (HAART) (osteonecrosis, osteoporosis, myopathy). Any musculoskeletal disorder present in an HIV-negative patient can occur in an HIV-infected patient. However, its clinical presentation and the course of illness may be varied. Table 81.1 enumerates the common rheumatic manifestations of HIV and AIDS.

### Clinical Features

#### DIRECTLY RELATED TO HIV INFECTION

##### Joint Disorders

##### Arthralgias

This is the most common manifestation seen in more than 40% of cases.<sup>3</sup> Knees, shoulders, and elbows are the most frequently involved joints. Arthralgias and myalgias may present during the acute seroconversion phase or may appear in advanced stages of HIV infection. Proper counseling with reassurance and use of analgesics like paracetamol form the mainstay of treatment. The pathogenesis involves release of cytokines or transient bone ischemia.<sup>4</sup> These patients presenting with only arthralgias rarely progress to inflammatory joint disease. Recently, with the increasing use of protease inhibitors (indinavir, ritonavir, saquinavir), there is a rise in the incidence of non-specific arthralgias.<sup>5</sup>

**Table 81.1:** Rheumatic Manifestations of HIV

#### Directly related to HIV infection

HIV-associated joint disorders  
HIV-associated muscle disorders  
HIV-associated vasculitis  
Diffuse infiltrative lymphocytosis syndrome  
Serologic abnormalities  
Miscellaneous conditions

#### Consequence of immunosuppression

Septic arthritis  
Osteomyelitis  
Pyomyositis  
Soft-tissue infection

#### Related to treatment with HAART

Myopathy  
Rhabdomyolysis  
Fibromyalgia  
Carpal tunnel syndrome  
Enthesitis  
Hypertrophic osteoarthropathy  
Gout  
Osteonecrosis  
Osteoporosis  
Frozen shoulder  
Dupuytren disease  
Mycobacterial and mycotic osteoarticular disease

#### Diseases going into remission

Rheumatoid arthritis  
Systemic lupus erythematosus

##### Arthritis

It is usually an oligoarthritis, predominantly involving lower limbs, acute in onset, self-limiting, non-erosive, and lasting for less than 6 weeks.<sup>6,7</sup> Its incidence varies from 30% to 35%.<sup>8–10</sup> It is most commonly seen in sub-Saharan Africa. Commonly involved joints are knees, ankles, and metatarsophalangeal joints in lower limbs and wrists, elbows, metacarpophalangeal, and interphalangeal joints in the upper limbs. There is no association with HLA-B<sub>27</sub> or any other known genetic factor. Synovial fluid cultures are sterile. There may be a direct role of HIV as shown by the presence of tubuloreticular inclusions

in synovial fluid by electron microscopy.<sup>6,7,11</sup> Radiographs of the affected joints are invariably normal. Rarely, it may show joint-space narrowing and destruction with prolonged symptoms. Treatment includes non-steroidal anti-inflammatory drugs (NSAIDs) for 6 weeks and in severe cases, low-dose glucocorticoids (prednisolone 7.5–10 mg/day for 2 weeks) may be tried. Hydroxychloroquine 200–400 mg/day and Sulfasalazine 500 mg to 2 g/day can be used if there is no response to NSAIDs and steroids.<sup>12</sup> Jaccoud arthropathy, a non-erosive deforming arthropathy reported in systemic lupus erythematosus (SLE) and chronic rheumatic fever, has also been reported in HIV-infected patients.<sup>13</sup>

### Painful Articular Syndrome

It is a self-limited syndrome of unknown etiology lasting less than 24 hours, characterized by severe bone and joint pains.<sup>6</sup> It predominantly occurs in the late stages of HIV infection. The knee is the most commonly affected joint followed by elbow and shoulder. There is absence of synovitis, and radiographs may be normal or occasionally periarticular osteopenia may be seen. It responds well to analgesics like paracetamol 500 mg tds.

## Seronegative Spondyloarthropathies

### Undifferentiated Spondyloarthropathy

HIV-infected patients most commonly suffer from undifferentiated spondyloarthropathy as described by Solomen et al.<sup>14</sup> This type of arthropathy has features like reactive arthritis or psoriatic arthritis (PsA) but does not develop full-blown features like enthesopathy or Achilles tendonitis or plantar fasciitis. It can be treated with indomethacin 75 to 150 mg/day, local intralesional steroids, and rarely require sulfasalazine 1.5 to 2 g/day.

### Reactive Arthritis, Reiter Syndrome

The pandemic of HIV infection in Africa has resulted in an increased incidence of different types of arthritis. The risk factors for these arthritides differ in Africa and the Asian countries where heterosexual transmission is a more common cause of HIV transmission than homosexual transmission or intravenous drug abuse as seen in the western world. The clinical features, diagnostic, and radiological features are similar to HLA-B<sub>27</sub>-related arthritis. The typical presentation is lower-extremity peripheral arthritis, enthesitis, dactylitis (sausage digits), Achilles tendonitis, plantar fasciitis, keratoderma blennorrhagica, circinate balanitis, and psoriaform rashes. Asymmetrical knee or ankle involvement, clinically asymptomatic sacroilitis, which may be seen radiologically, are the commonest joints affected. The triad of urethritis, arthritis, and uveitis is commonly seen as in HIV-negative patients.

The immunopathogenesis of Reiter syndrome is linked to HLA-B<sub>27</sub>.<sup>15</sup> The association of HIV and Reiter syndrome can be explained by severe immunosuppression, which predisposes to the presence of arthritogenic microorganisms. HIV patients are more prone for gastrointestinal and genitourinary infections (*Shigella*, *Entamoeba*, *Giardia*, *Chlamydia* etc). The course of

Reiter syndrome may be severe, progressive, and refractory to treatment than in HIV-negative patients.<sup>16</sup>

The mainstay of treatment of Reiter syndrome includes indomethacin 75–150 mg/day and sulfasalazine 1.5–2 g/day. Some patients respond to hydroxychloroquine 200–400 mg/day and HAART. Methotrexate and azathioprine are best avoided as they can cause severe immunosuppression; however, they can be used with careful monitoring of CD4 counts and viral load.

### Psoriatic Arthritis (PsA)

The articular disease is either sustained, aggressive, and progresses to erosions or it is characterized by mild and intermittent joint involvement. PsA may be severe in HIV-infected individuals. There is an increased prevalence of PsA in HIV patients.<sup>9,17,18</sup> The arthritis is polyarticular disease involving lower limbs mainly foot and ankle presenting as enthesopathy and dactylitis. The sacroiliac and spinal joints are also commonly affected. Frank synovitis and effusions are less frequent. Nail involvement is commonly associated with arthritis of distal interphalangeal joint.

The course of psoriatic arthropathy during HIV infection is variable but tends to progress with the decrease in the CD4 count and appears to be refractory to conventional treatment. In this regard, the presence of psoriasis can be considered as a sign of poor prognosis in HIV infection.<sup>19,20</sup> HIV infection can precipitate or worsen pre-existing psoriasis and the appearance of new psoriatic lesions is a well-recognized cutaneous manifestation of HIV. Seborrhoeic dermatitis occurs in up to 20% of patients with HIV infection and its overlap with psoriasis (so-called seborrhoeic psoriasis) is an uncommon but highly characteristic manifestation of HIV infection.<sup>21</sup>

Indomethacin is used as an anti-inflammatory agent. Phototherapy with ultraviolet A can result in control of skin rash but increases viral replication. Methotrexate, sulfasalazine, HAART, tumor necrosis factor- $\alpha$  blockers, cyclosporine, etretinate can be used with close monitoring of CD4 count and viral load.

## HIV-Associated Muscle Disorders

Muscle disease was one of the first rheumatic complications to be seen in HIV-positive patients and there is a spectrum of muscle disease associated with this infection.<sup>22</sup> Muscle involvement ranges from myalgias, fibromyalgias to disabling HIV-associated polymyositis (PM) or pyomyositis. Various HIV-associated muscle disorders are listed in Table 81.2.

**Table 81.2:** HIV-Associated Muscle Disorders

Myalgias and fibromyalgias
Polymyositis
Nemaline rod myopathy
HIV associated wasting syndrome
Treatment related myopathies
Infections like pyomyositis, Toxoplasmosis
Rhabdomyolysis
Tumor infiltrations of skeletal muscle
Inclusion body myositis

**Myalgias and Fibromyalgias**

About one-third of the HIV-positive patients complain of myalgias<sup>9</sup> and 11% complain of fibromyalgias.<sup>23</sup> They are treated with analgesics, tricyclic antidepressants, or selective serotonin reuptake inhibitors as in HIV-negative patients.

**Inflammatory Myopathies**

HIV-associated Polymyositis (PM) presents as subacute progressive proximal muscle weakness in upper and lower limbs with more predilection for lower limbs as seen in HIV-negative patients. Ocular, facial, and pharyngeal muscles are spared.<sup>24</sup> It may be seen early in HIV disease or as a part of immune reconstitution inflammatory syndrome (IRIS).<sup>22</sup> HIV-associated PM tends to respond to much lower doses of corticosteroids (0.5 mg/kg of oral prednisolone) than in patients with idiopathic PM. Refractory cases may require methotrexate, azathioprine, mycophenolate mofetil, or intravenous immunoglobulins.

**Nemaline Rod Myopathy<sup>25</sup>**

It is a diagnosis made after muscle biopsy. It is seen in congenital and acquired myopathies. The presence of atrophic type I fibers with numerous intracytoplasmic rod bodies seen on EM are the characteristic muscle biopsy features. Its presence should arouse the suspicion of HIV infection. Steroids may be helpful in some cases.<sup>26</sup>

**HIV-Associated Wasting Syndrome**

It has been associated with progressive weight loss and an active non-inflammatory myopathy. It is also called as “slim disease” in Africa.<sup>26</sup> Treatment consists of corticosteroids, anabolic steroids, human growth hormone, nutritional supplements, and cytokine antagonists.

**Treatment-Related Myopathies**

The use of nucleoside analogs for the treatment of HIV infection has been associated with myopathy. Fifteen to forty percent patients receiving zidovudine (AZT) develop increased serum concentrations of creatine phosphokinase, clinical myositis with myalgias, or weakness or both. It may be difficult to distinguish this condition clinically from HIV-associated PM. Dalakas et al<sup>25</sup> have demonstrated that muscle biopsy is helpful in differentiating AZT-related myopathy from HIV-associated PM. Numerous ragged-red fibers indicative of abnormal mitochondria with paracrystalline inclusions were found in the muscle biopsy of patients treated with AZT only. AZT-induced mitochondrial damage with cytochrome oxidase deficiency has also been reported in literature.<sup>27</sup> Stoppage of the drug can cause reversal of this myopathy within 4 to 8 weeks.

Recently, a few cases have been reported with a syndrome of hepatic steatosis, lactic acidosis, and myopathy with increased creatine phosphokinase in patients taking stavudine.<sup>28</sup> Direct mitochondrial injury is postulated as the underlying mechanism.

The muscle biopsy is suggestive of abundance of lipid droplets with associated muscle inflammation.

**Rhabdomyolysis**

It can occur in all the stages of HIV. It may be seen in primary HIV infection or it can occur with opportunistic infections of the muscles or it may be drug induced. Drugs like didanosine, lamivudine, ritonavir, indinavir, and trimethoprim-sulfamethoxazole can cause rhabdomyolysis.<sup>29</sup>

**Inclusion Body Myositis**

It is a well-recognized complication of HIV infection.<sup>30</sup> Its clinical features and treatment are similar to sporadic inclusion body myositis as seen in HIV-negative patients.

**HIV-Associated Vasculitis**

Different patterns of vasculitis have been described in patients with HIV infection. Small-vessel vasculitis presents as peripheral neuropathy (leukocytoclastic vasculitis) often misdiagnosed as drug toxicity (hypersensitivity angitis)<sup>24</sup> or as Henoch–Schönlein purpura. Medium-vessel involvement presents as polyarteritis nodosa, which is the most common type of vasculitis seen in HIV patients. Large-vessel involvement presents as giant cell arteritis (very rare), Wegener granulomatosis, and vasculitis causing aneurysm of aorta and its primary branches such as carotid, femoral, and superior mesenteric arteries. Cytomegalovirus vasculitis, Kawasaki disease, and cryoglobulinemia have also been described in HIV patients. In children, a cerebral vasculopathy with microaneurysm formation is commonly seen.<sup>31</sup> A large-vessel aneurysmal vasculitis has been exclusively reported from Africa.<sup>32,33</sup> Behcet syndrome and relapsing polychondritis have been reported in anecdotal case reports and they respond to HAART.<sup>34</sup>

Although anti-neutrophilic cytoplasmic antibodies (ANCA) have been described in HIV-seropositive patients, these antibodies do not have a role in the pathogenesis of HIV-associated vasculitis. Immunoglobulin M and complement have been demonstrated in vessel walls, which suggest immune-complex deposition as the possible pathogenetic mechanism of vasculitis in HIV.<sup>35</sup> Whether HIV itself can cause vasculitis is unclear.

Whether HIV and vasculitis have a casual association or they occur coincidentally is not yet understood. HIV-associated vasculitis is usually not life-threatening and presents as single flare rather than relapsing illness. Hepatitis B and C should be ruled out in all HIV-associated vasculitis. Corticosteroids form the mainstay of the treatment. Immunosuppressants are given for resistant cases with careful monitoring of CD4 and viral load. Intravenous immunoglobulins and plasmapheresis should be considered in advanced immunosuppression and progressive vasculitis in HIV cases. Anti-CD25 is effective for cerebral vasculitis associated with HIV infection.<sup>36</sup> There are very few reports on the efficacy of HAART in the treatment of HIV-associated vasculitis.

## Diffuse Infiltrative Lymphocytosis Syndrome (DILS)

A syndrome similar to Sjogren syndrome characterized by massive and painless parotid gland enlargement, xerostomia, extraglandular features (lymphocytic interstitial pneumonia, renal tubular acidosis, lymphocytic hepatitis, lymphocytic meningitis, facial palsy) and peripheral CD8+ lymphocytosis has been described commonly in HIV-positive patients. It can appear at any stage of HIV disease. The frequency of DILS ranges between 3% and 78% as reported in different series.<sup>37,38</sup> The diagnosis is made by the presence of HIV seropositivity by ELISA and western blot, bilateral salivary gland enlargement or xerostomia lasting for more than 6 months, salivary or lacrimal gland histology showing lymphocytic infiltration in the absence of granulomatous, or neoplastic enlargement.<sup>39</sup> Anti-nuclear antibody (ANA), SSA (anti-Ro)/SSB (anti-La), and rheumatoid factor are usually negative. Men are more commonly affected than females and extraglandular features are more commonly seen than Sjogren syndrome. Computerized tomography scan of salivary glands may be helpful in ruling out cysts or malignancy. The treatment consists of reassurance, artificial saliva (mouth spray), pilocarpine 5 to 10 mg tds, prednisolone 30 to 40mg/day, and maintenance of dental care. The glandular swelling responds well to HAART.

## Serological Manifestations

In early disease, HIV predominantly infects macrophages. There is an increased production of proinflammatory cytokines, lymphocyte proliferation, and B-cell activation to produce hypergammaglobulinemia and autoantibodies. These are ANA, anti-erythrocyte, anti-CD4 lymphocyte, anti-platelet, rheumatoid factor, anti-protein S, anti-cardiolipin, and ANCA.<sup>40</sup> Most prominent amongst these are anti-phospholipid antibodies, immunoglobulin G, and immunoglobulin M. Although these antibodies are seen commonly in HIV patients, they rarely give rise to thrombotic phenomena. ANA are seen in 10–30% of HIV patients. These antibodies are usually present in low titers. They occur in patients with advanced HIV infection, low CD4 counts, and are associated with increased mortality.<sup>41</sup> Thus, the presence of most of these antibodies, indicate B-cell activation. They are not actually involved in the pathogenetic mechanisms. The few autoantibodies that are pathogenic include anti-platelet/anti-erythrocyte, which cause immune thrombocytopenic purpura and hemolytic anemia in a minority of patients.

## Miscellaneous Rheumatic Conditions

Osteonecrosis, hypertrophic osteoarthropathy, Behcet syndrome, Sweet syndrome, adult onset Still's disease, heterotropic ossificans, and primary pulmonary hypertension have been described in HIV-infected patients.<sup>42</sup> Hypertrophic pulmonary osteoarthropathy is seen in patients with *Pneumocystis jiroveci* pneumonia and resolves with treatment of pneumonia.<sup>43</sup> Primary pulmonary hypertension is more commonly seen in younger patients with

AIDS. The responses to vasodilator agents like calcium channel blockers, sildenafil, intravenous and inhaled prostanoids, and endothelin antagonists are promising in the treatment of primary pulmonary hypertension.

## CONSEQUENCE OF IMMUNOSUPPRESSION

Musculoskeletal infections can occur as an effect of immunosuppression. The incidence of these infections has been reported to be less than 1% in a large series.<sup>24,44–46</sup> The various musculoskeletal infections are septic arthritis, soft-tissue infections like cellulitis and pyomyositis, osteomyelitis, and rarely septic bursitis.

## Septic Arthritis

It may be the first manifestation of AIDS when CD4 cell count falls to less than 100/ $\mu\text{L}$ .<sup>3</sup> Acutely swollen; painful; tender, red, hot joint, accompanied by systemic symptoms of bacteremia is the typical presentation. *Staphylococcus aureus*, *Stenotrophomonas maltophilia*, *Prototheca wickerhamii*, and *Candida albicans* are common organisms causing septic arthritis.<sup>47</sup> The important risk factors for septic arthritis are IV drug abuse, previous intra-articular injection or synovial fluid aspiration from the joint, psoriasis or pustular skin infection around the joints. Intracellular organisms like *Mycobacterium tuberculosis*, *M. kansasii* and *M. avium*; fungi like *Candida albicans*, Cryptosporidia, Histoplasma and Pseudomonas are the common pathogens in IV drug abusers. Gonococci is the organism common in patients who have received intra-articular injections or synovial fluid has been aspirated. With impaired immune response of the host, the signs of inflammation may be minimal. Hence, it is important to examine the synovial fluid of every HIV-positive patient having joint effusion.

In a study of 43 cases of hemophiliacs with Patients of hemophilia with AIDS can develop septic arthritis. In a study reported by Barzilia et al., the clinical features of septic arthritis in hemophiliacs with AIDS resemble those of hemarthrosis. In both these conditions, there is high ESR, fever and the affected joint is warm, tender and swollen. However, in these patients there is absence of peripheral leukocytosis and the CD4 count is variable. Treatment with systemic antibiotics is sufficient and arthrotomy and open drainage is rarely required.<sup>48–51</sup>

## Soft-Tissue Infections

Although rare, these range from cellulitis, soft-tissue abscesses to pyomyositis. They occur when CD4 cell count falls to less than 200 cells/ $\mu\text{L}$ .<sup>3</sup> Intravascular indwelling catheters, trauma, and extra-articular infection are the predisposing factors.<sup>52</sup> The clinical features and treatment outcome are almost similar to that in HIV-negative patients.

## Tropical Pyomyositis

It is an acute bacterial infection of skeletal muscles characterized by rapid formation of abscesses. Acute onset unilateral thigh pain

with swelling, erythema, and woody induration are the typical clinical features. It can simulate septic arthritis of knee and hip as the thigh muscles are commonly involved. Ultrasonography, computerized tomography, or magnetic resonance imaging of the affected part with aspiration of pus confirms the diagnosis. Occurrence of tropical pyomyositis is a criterion for classifying HIV-infected patients in WHO stage III. The most common organism is *Staphylococcus aureus*<sup>53</sup> followed by *Salmonella*.<sup>54</sup> Other organisms are *Streptococcus pneumoniae*, *Citrobacter freundii*, and *Microsporidia*.

## Osteomyelitis

Clinical features are similar to septic arthritis. But it is usually associated with a poor prognosis and requires more prolonged treatment with antibiotics. Bacillary angiomatosis osteomyelitis is a disease seen only in HIV-positive patients.<sup>4</sup>

## Tuberculosis

Tuberculosis is one of the most virulent opportunistic infections and it appears fairly early in HIV disease. HIV specifically eliminates macrophages and CD4 cell count that provide immunity against tuberculosis. Musculoskeletal manifestations may occur in 2% of cases. These are spondylitis, osteomyelitis/mono-oligo-polyarthritis,<sup>55</sup> Poncet disease, and tuberculous dactylitis. Infectious arthritis and tenosynovitis are caused by *M. kansasii*. *M. xenopi* causes spondylodiscitis in AIDS patients. Also, the drugs used for the treatment of tuberculosis can give rise to rheumatic conditions. For example, rifabutin or clarithromycin can precipitate uveitis, fluoroquinolones can cause tendonitis, and pyrazinamide can lead to hyperuricemia and gout.

## RHEUMATIC MANIFESTATIONS OCCURRING AFTER HAART

A dramatic change has taken place in the treatment of HIV infection after the introduction of HAART. Although HAART has extended life expectancy in HIV-infected patients, it is not free from complications. These complications include both metabolic and inflammatory disorders, which may present as rheumatic manifestations.

## Metabolic Complications

### Osteonecrosis

Four percent of HIV-positive patients may have osteonecrosis.<sup>56</sup> It is one of the late complications of HIV. Osteonecrosis or avascular necrosis of the bone occurs due to impairment of blood supply to bone. Tissue necrosis takes place in the subchondral bone, which may ultimately lead to compression and deformity of the articular surface. Various studies have demonstrated significant associations with the use of glucocorticoids, lipid-lowering agents, anabolic steroid use, protease inhibitors-based HAART treatment, alcohol abuse,

and hypercoagulability.<sup>57</sup> The most common presenting symptom is pain on weight-bearing. Some patients may be asymptomatic and diagnosis is made by radiological studies.

### Osteoporosis

Osteopenia and osteoporosis occur more than 3 times as commonly in HIV-infected patients regardless of HAART<sup>58</sup> and can result in pathologic fractures. Risk factors for the development of osteopenia are use of protease inhibitors, longer duration of HIV infection, high viral load, high lactate levels, low bicarbonate levels, increased alkaline phosphatase levels, and lower body weight before HAART.<sup>59</sup> The role of HAART as a contributing factor in the development of osteopenia or osteoporosis is controversial.<sup>60</sup> Some authors have attributed abnormal bone metabolism to the HIV infection itself.<sup>61</sup> Bisphosphonates, calcium, and vitamin D are used to preserve bone density.

### Gout

Abnormalities in urate metabolism have been described in HIV-positive patients. Asymptomatic hyperuricemia can occur in 41% and symptomatic hypouricemia in 5%. Acute gout attacks have also been described. Asymptomatic hyperuricemia and gout are commonly seen in patients who receive ritonavir as a boosted protease inhibitor and who also have lipodystrophy.<sup>62</sup>

## Autoimmune/Inflammatory/Infectious Complications

The introduction of HAART in a patient with HIV infection is followed by suppression of HIV replication and a rise in peripheral CD4 lymphocyte counts and a varying degree of immune restoration. This leads to an inflammatory reaction to occult pathogens in 20–25% of patients with advanced disease known as IRIS or immune restoration disease.<sup>63</sup> In a recent review of 32 cases, sarcoidosis, autoimmune thyroid disease, Reiter syndrome, and various connective tissue diseases like RA, SLE, and PM have been reported.<sup>64</sup> The mean time from the introduction of HAART to the appearance of clinical autoimmune/inflammatory disease is approximately 9 months and most cases are mild or self-limiting and resolve with little or no therapy.<sup>65</sup>

Mycobacterial and mycotic osteoarticular infection, neoplasia, rhabdomyolysis, septic arthritis, cellulitis, osteomyelitis, discitis, pyomyositis, fibromyalgia, seronegative symmetrical polyarthritis, carpal tunnel syndrome, enthesitis, multifocal bone non-Hodgkin lymphoma, and hypertrophic osteoarthropathy have been reported in anecdotal case reports as rheumatological manifestations after starting HAART.

Indinavir-associated monoarthritis,<sup>66</sup> frozen shoulder, temporomandibular joint dysfunction, and Dupuytren disease<sup>5</sup> have been reported in literature. With the advent of HAART, there is an increase in life expectancy, but new rheumatic complications such as osteonecrosis, osteoporosis, gout, mycobacterial, and mycotic osteoarticular infections may become more prevalent.

## AUTOIMMUNE DISEASES GOING INTO REMISSION OR LESS COMMONLY SEEN IN HIV

### Systemic Lupus Erythematosus

HIV patients can share many clinical, laboratory, and serological findings as seen in SLE. Concomitant HIV infection and SLE have been reported although rare.<sup>67</sup> Lupus-like syndrome has been described in HIV. The significance of presence of different types of autoantibodies in HIV-infected patients is still uncertain and may reflect polyclonal B-cell activation as discussed earlier. Autoantibodies like ANA, anti-double-stranded DNA (anti-dsDNA), anti-Smith antibody, anti-parietal cell, anti-glomeruli, anti-thyroid, and ANCA<sup>41</sup> also occur frequently in both diseases. Although, theoretically, both these diseases would be mutually exclusive, SLE should be considered in HIV-positive patients with rheumatologic complaints.<sup>8</sup>

HIV infection can result in clinical improvement of the disease activity in lupus patients and disappearance of autoantibodies when the CD4 cell counts are low.<sup>67</sup> A clinical improvement can also occur when CD4 cell counts are normal. Treatment with ART leads to restoration of the immune system which can flare SLE.<sup>67</sup> Conversely, SLE treatment with immunosuppressive drugs can lead to HIV replication and rapid progression in the clinical course of HIV.<sup>68</sup> Treatment of the two conditions is decided on the basis of individual patient with careful monitoring of the CD4 cell count, viral load, autoantibodies, ESR, C-reactive protein, complement levels, and the clinical response to treatment.

### Rheumatoid Arthritis

Patients with RA who go into remission after HIV infection with clinical immunosuppression have been reported.<sup>69,70</sup> CD4 cell count depletion is the postulated mechanism. RA patients having active disease and radiologic progression despite an immunosuppressive state of HIV infection, have also been described.<sup>71,72</sup>

### Antiphospholipid Antibody Syndrome

False-positive syphilis tests and the lupus anticoagulant have been reported in 40–50% of HIV-positive patients in advanced stages.<sup>73</sup> High titers of anticardiolipin antibodies have been detected in a significant proportion of HIV-positive patients who are clinically asymptomatic. The immunoglobulin G anticardiolipin antibodies isotype has been found in 85–95% of patients with advanced HIV infection.<sup>74</sup> One study has reported high frequency of anti-phospholipid antibodies particularly for isotype IgA anti- $\beta_2$  glycoprotein.<sup>75</sup> However, there was no association with clinical manifestations of antiphospholipid antibody syndrome.

### Conclusion

Thus, HIV-infected patients can have similar rheumatologic conditions as seen in HIV-negative patients. Management of these conditions can pose difficulties to the treating physician/

rheumatologist as the immunosuppressive agents can rapidly cause full-blown AIDS in HIV-infected patients. These drugs are to be used cautiously with careful monitoring of the viral load and CD4 cell counts. With the availability of HAART, some inflammatory conditions undergo remission but IRIS, infections, and metabolic complications of HAART manifesting as rheumatological disorders should be kept in mind due to their rising incidence.

#### Summary

- Rheumatic manifestations can develop during the course of HIV infection at any stage of the disease but are more often seen in the late stages of the disease. These range from non-inflammatory pain syndromes, non-specific inflammation, autoimmune diseases like vasculitis, Sjogren syndrome called diffuse infiltrative lymphocytosis syndrome (DILS) to infectious rheumatic diseases (osteomyelitis, pyomyositis, septic arthritis), and those resulting from initiation of highly active antiretroviral therapy (HAART) (osteonecrosis, osteoporosis, myopathy).
- Several serological markers like ANA, rheumatoid factor, antiphospholipid antibodies may be found in the serum of HIV-positive patients in the absence of the clinical features.
- With the advent of HAART, there is an increase in life expectancy; but new rheumatic complications such as osteonecrosis, osteoporosis, gout, mycobacterial, and mycotic osteoarticular infections may become more prevalent.
- Management of the rheumatological conditions can pose difficulties to the treating physician/rheumatologist as the immunosuppressive agents can rapidly cause full-blown AIDS in HIV-infected patients.

# Cardiac Involvement in HIV Infection/AIDS

Yash Paul Sharma • Rakesh Raman Patyar

# 82

## Introduction

Acquired immune deficiency syndrome (AIDS) is a global health crisis affecting approximately 33.3 million people worldwide. In 2009, AVERT (formerly known as the AIDS Education and Research Trust) estimated approximately 1.8 million annual deaths due to AIDS and 2.6 million new HIV infections per year. AIDS progressively reduces the effectiveness of the immune system thereby making patients more susceptible to opportunistic infections and tumors. Advances in highly active antiretroviral therapy (HAART) have reduced both the mortality and the morbidity of HIV infection. Although HIV infection has been associated with cardiac manifestations since pre-HAART era, reports of increased incidence of cardiovascular manifestations after the introduction of HAART and also due to increased life span have raised serious concerns. Various studies have indicated that HAART is associated with an increase in both peripheral and coronary arterial diseases. Moreover, the association of HIV with cardiac manifestations has become so evident and common that it is being considered as a potential risk factor for coronary artery disease. However, the risk of cardiac involvement is quite variable as it depends on a variety of factors like the stage of HIV disease, the immune-status of the patient, type of drugs being used to treat the disease, and the presence of opportunistic infections or neoplasms. The cardiac manifestations associated with HIV include coronary artery disease, dilated cardiomyopathy (DCM), pericardial effusion, pulmonary hypertension leading to heart failure, conduction system abnormalities, and neoplastic infiltration. A variety of mechanisms have been implicated in this association. But the principal underlying causes are direct invasion by HIV as well as the occurrence of opportunistic infections.

Here we will discuss the issues regarding the principal HIV-associated cardiovascular manifestations, their potential causes/mechanisms (Table 82.1), prevalence, pathogenesis, and management. Due to lack of proper guidelines, there is a growing need for generating awareness so that HIV-associated cardiovascular diseases can be diagnosed, prevented, or treated early in the course.

**Table 82.1:** Principal Cardiac Diseases in HIV-infected/AIDS Patients Along with Their Potential Causes

Type	Potential causes
<b>Myocardial diseases</b> HIV-associated dilated cardiomyopathy	<b>Infection leading to myocarditis</b> HIV, Coxsackie virus group B, Epstein–Barr virus, cytomegalovirus, adenovirus <b>Drug-related cardiotoxicity</b> Zidovudine and phosphorylated azidothymidine <b>Autoimmunity</b> Anti- $\alpha$ -myosin antibodies <b>Nutritional deficiencies</b> Selenium, carnitine, vitamin B <sub>1</sub> and B <sub>12</sub> <b>Endocrine</b> Growth hormone and thyroid hormone
<b>Endocardial diseases</b> Infective endocarditis	<b>Bacteria</b> <i>Staphylococcus aureus</i> , <i>Streptococcus pneumoniae</i> , and <i>Haemophilus influenzae</i> <b>Fungus</b> <i>Candida albicans</i> , <i>Aspergillus fumigatus</i> , and <i>Cryptococcus neoformans</i> Rheumatic fever, hypercoagulable states, and trauma (e.g., catheters)
Nonbacterial thrombotic endocarditis	
<b>Pericardial diseases</b> Pericardial effusion	HIV itself, opportunistic infections Malignancies (Kaposi sarcoma, non-Hodgkin lymphoma)
Pericarditis	HIV itself, opportunistic infections
<b>Vascular diseases</b> Atherosclerosis	<b>Dysfunctional endothelial cells</b> Potentiate tissue injury, inflammation, and remodeling <b>Virus infected monocyte macrophages</b> Alter leukocyte adhesion or arteritis Recurrent bronchopulmonary infections, pulmonary arteritis Microvascular pulmonary emboli due to thrombus or drug injection Mediator release from endothelium
Pulmonary hypertension	

continued on next page

Type	Potential causes
<b>Coronary artery disease</b>	<b>Endothelial cells</b> Alter the procoagulant, anticoagulant, and fibrinolytic pathways Unusual proliferation of smooth muscle cells, mixed with abundant elastic fibers Side-effects of combined antiretroviral therapy Coronary arteriopathy
<b>Cardiovascular malignancies</b>	Kaposi sarcoma Non-Hodgkin lymphoma
<b>Cardiac arrhythmias</b>	
Prolonged QTc interval	<b>Protease inhibitors</b> Block the human ether-a-go-go related gene channel
Torsades de Pointes	<b>Antiretroviral drugs such as pentamidine</b> Hypomagnesemia

## HIV-Associated Cardiovascular Manifestations

### MYOCARDIAL DISEASE

HIV disease is considered as a potential risk factor of dilated cardiomyopathy (DCM). DCM had been described in up to 30–40% of patients with AIDS in clinicopathological studies performed in the pre-HAART period.<sup>1</sup> The median survival was found to be 101 days in patients with left ventricular dysfunction compared with 472 days in HIV infected patients with a normal echocardiogram at the same stage of infection.<sup>2</sup> DCM occurs late in the course of HIV infection and is caused by a complex and multifactorial mechanism. The most important cause is myocarditis which itself is secondary to HIV or other infectious agents. HIV-1 virions infect myocardial cells thereby leading to progressive cardiac myocyte dysfunction. Another major cause for the development of HIV-associated DCM is the cardiotoxicity of drugs used in HIV infection, e.g., zidovudine and phosphorylated azidothymidine. As increased levels of anti- $\alpha$ -myosin antibodies have been reported in patients with HIV-associated cardiomyopathy cardiac autoimmunity too has been implicated in its pathogenesis. Nutritional deficiencies (selenium, carnitine, vitamin B<sub>1</sub> and B<sub>12</sub>) which are very common in HIV infection are also held responsible for development of DCM as they contribute in inducing ventricular dysfunction independently of HAART regimens. Similarly, deficiencies of trace elements have been associated directly or indirectly with cardiomyopathy. Altered levels of growth and thyroid hormone also have been associated with left ventricular dysfunction. Gross pathologic features of HIV-associated DCM include endocardial fibrosis and mural thrombus, while histological features involve myocyte hypertrophy and degeneration, with increased interstitial and endocardial fibrillar collagen often associated with evidence of previous myocarditis. DCM may result in secondary mitral and tricuspid regurgitation also (Fig. 82.1 a & b).

The most sensitive and specific method for the evaluation of DCM is echocardiography. In a prospective study of 952 asymptomatic HIV positive patients, an echocardiographic

**Fig. 82.1 a & b:** 2-D color Doppler showing mitral and tricuspid regurgitation, respectively, in HIV cardiomyopathy. *Courtesy: Dr. Arun Gopi; PGIMER, Chandigarh.*

diagnosis of DCM was made in 76 (8%) patients with a mean annual incidence of 15.9/1000 patients. All patients with echocardiographic abnormalities underwent endomyocardial biopsy. Myocarditis was present in 63 (83%) of the patients with DCM and 36 (57%) of these had a positive hybridization signal for HIV. Coinfection with coxsackie virus, cytomegalovirus (CMV), and Epstein–Barr virus (EBV) was also noted in many cases.<sup>3</sup> In a recent study, echocardiographic findings were identified in 22 of 52 HIV-positive patients (42.3%). Eighteen patients (34.6%) were having decrease in fractional shortening, 10 patients (19.2%) had left ventricular diastolic dysfunction, 8 patients (15.4%) had global hypokinesia and pericardial effusion was present in 6 patients (11.5%). Nineteen out of 22 patients having CD4 cell count <100 cells/ $\mu$ L had echocardiographic abnormalities. Patients with opportunistic infections had more frequent echocardiographic abnormalities than those without

opportunistic infections ( $P < 0.001$  for TB, candidiasis and various pneumonias).<sup>4</sup> Echocardiography is helpful in detecting diastolic dysfunction in early disease. Computer tomography (CT) and magnetic resonance tomography (MRI) may help to clarify the etiology, especially in cases secondary to neoplastic infiltrations. However, the need for routine endomyocardial biopsy is controversial. ACE inhibitors and beta-blockers are recommended, but may be poorly tolerated because of low systemic vascular resistance due to associated diarrheal disease, infection, or dehydration. There is enhanced sensitivity to digoxin.

### ENDOCARDIAL DISEASE

HIV-associated endocardial diseases include nonbacterial thrombotic endocarditis as well as infective endocarditis. Vegetations form on the tricuspid and pulmonary valves with resultant pulmonary embolism and septic pulmonary infarction. Nonbacterial thrombotic endocarditis, also known as marantic endocarditis, occurs in 3–5% of AIDS patients with mostly having HIV related wasting syndrome. Here left sided valves are frequently affected, and the vegetations are mostly friable.<sup>5</sup> The prevalence of infective endocarditis varies from 6.3% to 34% in the HIV-infected patients who use intravenous drugs independent of HAART regimens.<sup>5</sup> In this case, right-sided valves are predominantly affected. *Staphylococcus aureus* (>75% of the cases) is the most common pathogen, followed by *Streptococcus pneumoniae*, *Haemophilus influenzae*, *Candida albicans*, *Aspergillus fumigatus*, and *Cryptococcus neoformans*. Since the introduction of HAART, marantic endocarditis is less frequent and has rarely been a cause of death in HIV-infected patients. Clinical presentation, diagnosis, and management of infective endocarditis in HIV-patients are similar to that seen in the general population. Medical therapy is successful in >70% of cases and surgery also has good outcome.

### PERICARDIAL DISEASE

The prevalence of pericardial effusion in asymptomatic HIV-positive patients is estimated at 11%.<sup>6</sup> There is no apparent correlation between clinical stages of HIV infection and severity of pericardial involvement. Pericardial effusions in HIV diseases may be related to HIV itself, opportunistic infections, or malignancies (Kaposi sarcoma, non-Hodgkin lymphoma), but most often a clear etiology is not found (Fig. 82.2). The pericarditis is usually nonspecific in origin and can occur with or without effusion. Low pressure tamponade may be encountered in patients with AIDS who are severely dehydrated and cachectic with low resting right ventricular filling pressures. Echocardiography is considered as the standard method for diagnosis and control of pericardial diseases. But in case a neoplasm or an increase in the cardiac lipid tissue is suspected, diagnosis should be performed by CT/MRI. Small asymptomatic effusions do not require diagnostic evaluation and spontaneously resolve in up to 42% of the patients. However, symptomatic patients may require pericardial puncture. Pericardiectomy may be considered as an option for palliative care.

**Fig. 82.2:** 2-D color Doppler showing HIV-associated pericardial effusion. Courtesy: Dr. Arun Gopi; PGIMER, Chandigarh.

### CARDIOVASCULAR MALIGNANCIES

Two types of malignancies affect the heart in patients infected with HIV, namely, Kaposi sarcoma and malignant lymphoma, of which former is more common. Kaposi sarcoma is a low grade neoplasm arising from mesenchymal or endothelial cells and occurs in approximately 30% of the patients with AIDS, mostly male homosexuals. It may cause visceral or parietal pericardial lesions and, less frequently, myocardial lesions. Cardiac Kaposi sarcoma is not associated with clinical cardiac dysfunction, morbidity, or mortality. It is usually occult and rarely diagnosed during life. Primary cardiac malignancy associated with HIV infection is generally due to cardiac lymphoma. Non-Hodgkin lymphoma is 25 to 60 times more common in HIV-infected individuals. Lymphomatous infiltration may be diffuse or may result in discrete isolated lesions, which are usually derived from the Burkitt or immunoblastic type B cells. Clinical manifestations of cardiac lymphoma include cardiomegaly, pericardial effusions, congestive heart failure, arrhythmias, and progressive heart block. Sudden death is rare. The prognosis is generally poor and the optimal approach to treatment has yet to be determined, though clinical remission has been obtained with combination chemotherapy.

### VASCULAR DISEASE

In HIV infection, dysfunctional endothelial cells potentiate tissue injury, inflammation, and remodeling, which further accelerates the development of cardiovascular diseases.<sup>7</sup> In HIV infected patients, because of atherogenesis stimulated by virus infected monocyte macrophages, there may be acceleration of vascular disease, possibly as a result of altered leukocyte adhesion or arteritis. The reported arterial lesions include arteriopathy with or without aneurysm formation, fibrocalcific lesions, and endothelial proliferation in association with Kaposi sarcoma. Primary pulmonary hypertension has been reported in disproportionate number of HIV infected individuals and is estimated to occur in 0.5% of the hospitalized patients with AIDS.<sup>8</sup> The pathogenesis of primary pulmonary hypertension in HIV infection is multifactorial and quite uncertain.

Isolated right ventricular hypertension with or without right ventricular dilation is generally related to pulmonary diseases that increase pulmonary vascular resistance, such as recurrent bronchopulmonary infections. The clinical symptoms and the outcome of patients with right ventricular dysfunction are related to the degree of pulmonary hypertension, varying from a mild asymptomatic condition to severe cardiac impairment and even death. The effect of HAART on pulmonary hypertension is not known; however, a recent study has reported that pulmonary artery pressure increased in untreated patients but decreased in HAART-treated patients. Similarly the effect of epoprostenol therapy on the prognosis of HIV-infected patients with pulmonary hypertension is not clear. However, it is generally used in seriously ill patients because of the need for continuous intravenous infusion with an associated risk of infection. The oral endothelin receptor antagonist, bosentan, has been reported to improve hemodynamic measurements in HIV patients.

### CORONARY ARTERY DISEASE AND HYPERTENSION

Coronary artery disease (CAD) is observed with increasing frequency among HIV-infected patients receiving HAART. Patients with pre-existing cardiovascular risk factors have a higher risk of developing acute coronary syndrome and stroke. However, data on the incidence of CAD among HIV-infected subjects receiving HAART is lacking. Presently, this information is limited to case reports. HIV-infected patients are at higher risk of developing hypertension at a younger age than the general population.<sup>9</sup> HIV-associated CAD is characterized by unusual proliferation of smooth muscle cells, mixed with abundant elastic fibers, resulting in endoluminal protrusions. Other factors responsible for CAD are endothelial cells and the side-effects of combined antiretroviral therapy. Endothelial cells act by altering the procoagulant, anticoagulant, and fibrinolytic pathways while altered adhesion of HIV-infected monocytes-macrophages and HIV-associated angiitis lead to coronary arteriopathy. Management of HIV-associated CAD employs changes in lifestyle, cessation of tobacco use, and treatment with atherogenic lipid profiles with dietary and pharmacologic interventions. HAART has been found beneficial too.

### METABOLIC SYNDROMES

HIV has been associated with the abnormalities of lipid metabolism, such as hypertriglyceridemia and low levels of high density lipoproteins since the pre-HAART era. However, after introduction of HAART, high levels of low-density lipoprotein and total cholesterol were reported. Hypertriglyceridemia can be treated with a fibrate, and a statin can be given for concurrent hypercholesterolemia. Similarly, the incidence and prevalence of diabetes mellitus has increased since the introduction of HAART. Furthermore, there is impaired glucose phosphorylation and transport in skeletal muscle in patients infected with HIV, with lipodystrophy as a mechanism of insulin resistance. A relatively

low dosage of metformin was reported to reduce insulin resistance and related cardiovascular risk parameters in patients infected with HIV who had lipodystrophy.

### CARDIAC ARRHYTHMIAS

HIV-associated cardiac arrhythmias may depend on medication. Prolonged QTc intervals and consequential Torsades de Pointes too have been associated with HIV infection. The underlying cause of this is yet unknown. Antiretroviral drugs such as pentamidine may cause hypomagnesemia and promote Torsades de Pointes, while protease inhibitors (PIs) block the human ether-a-go-go related gene (hERG) channel and prolong QT intervals.<sup>10</sup> Management employs initiation or change of such medications after controlled daily monitoring by ECG. Arrhythmias can be treated by electrolytes and glucose, if necessary. To terminate Torsades de Pointes tachycardia, magnesium may be used.

### Toxicity due to Antiretroviral and Other Medications

There are three classes of antiretroviral drugs presently being used for people with HIV infection: nucleoside reverse transcriptase inhibitors (NRTIs), non nucleoside reverse transcriptase inhibitors (NNRTIs), and PIs—given in various combinations. Drug-induced DCM secondary to mitochondrial toxicity has been associated with zidovudine use. However, from a clinical point of view, in a study of selected HIV infected children, zidovudine neither worsened nor ameliorated cardiac functions in patients with cardiomyopathy.<sup>11</sup> Recently, a study investigated the effect of antiretroviral therapy on carotid intima-media thickness in HIV-infected patients. The study concluded that HIV-infected patients treated with PIs show earlier vascular involvement as compared to those treated with NNRTIs, and healthy subjects with similar distribution of cardiovascular risk factors. However, during the 2-year follow-up in HIV-infected patients treated with PIs, no significant differences were observed.<sup>12</sup> Hyperlipidemia, hyperglycemia, hyperinsulinemia, and lipodystrophy are frequent adverse effects of potent antiretroviral combination therapies, particularly involving PIs, thus causing the complex clinical constellation termed lipodystrophy syndrome, consisting of abnormal fat redistribution and various metabolic alterations and ultimately accelerated atherosclerosis.

### TOXICITY DUE TO OTHER MEDICATIONS

Drugs used for HIV related diseases may also have adverse cardiac effects. Erythromycin, trimethoprim, and sulfamethoxazole may cause orthostatic hypotension. Antifungals can result in hypertension, arrhythmias, and hypokalemia. Pentamidine causes arrhythmias especially Torsades de Pointes (through QTc prolongation). Arrhythmias may be precipitated by the concomitant use of drugs that share the CY3PA metabolic pathway and clinicians should be aware of this potentially dangerous interaction.

## Cardiac Involvement in Children

The rate of vertical transmission has substantially decreased in the recent years owing to administration of antiretroviral therapy during pregnancy and delivery. Most pediatric patients with HIV are infected in the perinatal period. With the use of early screening echocardiography, rates of congenital cardiovascular malformations in both the HIV infected and HIV uninfected children were similar.<sup>13</sup> Rarely encountered cardiovascular manifestations of HIV infection in children include increased left ventricular mass with systolic dysfunction, myocarditis, vascular disease, aortic root dilatation, pericardial effusion, tumors, and minor ECG abnormalities.

## Conclusion

Cardiovascular diseases have been associated with HIV-infection both before and after the introduction of HAART. As the association of cardiac manifestations with AIDS is becoming evident, there is a need for thorough cardiological screening of such patients especially for those receiving HAART regimens and having other known underlying cardiovascular risk factors. Risk factors for cardiovascular manifestations should be aggressively modified/handled along with treatment of malnutrition, anemia, and wasting in HIV infected/AIDS patients for their better survival.

### Summary

AIDS is a global health crisis afflicting vital organs, including the cardiovascular system. The HIV infection has been associated with neurologic, pulmonary, and cardiac manifestations since pre-HAART era. However, the association of HIV with cardiac manifestations has become so evident after the introduction of HAART regimens that it is now being considered as a potential risk factor for coronary artery disease. Various other cardiac manifestations associated with HIV include dilated cardiomyopathy, pericardial effusion, and pulmonary hypertension leading to heart failure, conduction system abnormalities and neoplastic infiltration. Therefore, thorough cardiological screening of patients, especially for those receiving HAART regimens and having other known underlying cardiovascular risk factors, is being suggested as a critical preventive measure.

## Introduction

Acquired immunodeficiency syndrome (AIDS) was first described in 1981 and within 3 years the causative virus which is currently known as human immunodeficiency virus (HIV) was identified.<sup>1,2</sup> Several studies of ocular involvement in HIV/AIDS have been published from different parts of the world since the first description of ocular lesions in HIV-infected patients in 1982.<sup>3–7</sup> The first report of ocular manifestation of AIDS from India was published from Sankara Nethralaya, Chennai in 1995.<sup>8</sup> Since then two large series and a few other reports from different parts of India have been published.<sup>9–11</sup>

## Ocular Diseases in HIV Infection

Ocular diseases in HIV infection are varied and affect almost all structures of the eye. They manifest clinically in up to two-thirds of patients with AIDS at some point in their life time. However, at autopsy, 95% of AIDS patients have ocular lesions. Patients can have ophthalmic complaints during the early phase of HIV infection, and the ophthalmic manifestations of the disease can help the clinician suspect an underlying HIV infection. Ocular lesions can be classified on the basis of the involvement of various ocular structures (Table 83.1).<sup>12</sup> The frequencies of various ophthalmic manifestations in AIDS patients and their clinical presentations are shown in Table 83.2.

### ADNEXAL AND ANTERIOR SEGMENT LESIONS IN HIV INFECTION

Human immunodeficiency virus infection commonly affects the ocular adnexa. Anterior segment involvement may be the first clinical manifestation of HIV disease and it occurs in up to 50% of the patients.<sup>13</sup> The common conditions are described.

#### Herpes Zoster Ophthalmicus

Herpes zoster ophthalmicus (HZO) is caused by the varicella zoster virus and involves the ophthalmic distribution of the trigeminal nerve. Its occurrence in a person under 50 years of

**Table 83.1:** Ocular Lesions in Patients with HIV/AIDS

<i>A. Adnexal and anterior segment diseases</i>	
•	Herpes zoster ophthalmicus
•	Molluscum contagiosum of the eyelids
•	Lid infections
•	Conjunctival squamous cell carcinoma
•	Keratoconjunctivitis sicca
•	Infective keratitis (varicella zoster, herpes simplex, microsporidia)
•	Anterior uveitis
•	Ophthalmic Kaposi sarcoma
<i>B. Posterior segment diseases</i>	
•	Noninfectious HIV retinopathy
•	Opportunistic infections
•	Cytomegalovirus retinitis
•	Varicella zoster virus disease—acute retinal necrosis (ARN) and progressive outer retinal necrosis (PORN)

•	<i>Pneumocystis jiroveci</i> choroidopathy
<i>C. Orbital lesions</i>	
•	Orbital cellulitis
<i>D. Neuro-ophthalmic diseases</i>	
<i>E. Neoplasms</i>	

age should arouse the suspicion of an immunosuppressive state. Its prevalence in the HIV infected population is reported to be 5–15%.<sup>14</sup> Concurrent posterior segment involvement may also occur. Acute panuveitis with hemorrhagic hypopyon associated with HZO has recently been reported as the initial presenting feature of AIDS.<sup>15</sup>

Treatment consists of intravenous acyclovir (10 mg/kg, 3 times a day for 7–10 days) followed by an oral maintenance regimen (800 mg 5 times daily). Famciclovir can be used in a dosage of 500 mg, 3 times daily. Intravenous foscarnet should be considered if the response to acyclovir or famciclovir is not satisfactory.

#### Molluscum Contagiosum

Molluscum contagiosum is a contagious disease caused by a poxvirus. It clinically presents as multiple, small, painless,

**Table 83.2:** Estimated Frequency of Ocular Manifestations of AIDS.

Lesions	Frequency
<b>1. Microangiopathy</b>	
• Conjunctival microangiopathy	75%
• HIV retinopathy	50–67%
<b>2. Opportunistic ocular infection—anterior segment</b>	
• Microsporidial keratoconjunctivitis	<1%
• Herpes zoster ophthalmicus	4%
<b>3. Opportunistic ocular infection—posterior segment</b>	
• Cytomegalovirus	20–25%
• Varicella zoster virus retinitis (ARN, PORN)	<1%
• Toxoplasma retinochoroiditis	1%
• Choroidal pneumocystosis	<1%
<b>4. Ocular neoplasms</b>	
• Eyelid Kaposi sarcoma	1–2%
• Conjunctival Kaposi sarcoma	1–2%
• Orbital lymphoma	<1%
• Neuro-ophthalmic lesions	10%

umbilicated lesions, which are larger and more numerous in HIV positive individuals.<sup>16</sup> Lid involvement may be seen in up to 5% of patients and may be associated with a lid abscess as a result of secondary bacterial infection (Fig. 83.1).<sup>17</sup> Treatment options include cryotherapy, curettage, incision, and excision.<sup>18</sup>

### Lid Infections

Severe blepharitis, sty, and lid ulceration may occur as initial manifestations of ocular involvement in AIDS.<sup>19</sup> Treatment with antibiotics along with lid hygiene needs to be continued for a longer duration in these patients than in seronegative individuals.

**Fig. 83.1:** Molluscum contagiosum on the lids and face in a HIV-positive patient.

### Conjunctival Squamous Cell Carcinoma

Conjunctival squamous cell dysplasia and neoplasia have been associated with HIV infection and AIDS in the sub-Saharan African population.<sup>20</sup> Squamous cell carcinoma was reported in a healthy young patient, who was later found to be positive for HIV-2 infection.<sup>21</sup> Any rapidly growing mass on the conjunctiva should arouse the suspicion of an immunosuppressive condition.

### Keratoconjunctivitis Sicca

Keratoconjunctivitis sicca occurs in 10–20% of patients with HIV infection.<sup>22</sup> This is probably secondary to the destruction of the primary and secondary lacrimal glands as a result of either HIV mediated inflammation or an autoimmune pathology. Treatment is directed towards providing symptomatic relief using artificial tear substitutes and lubricating ointments.

### Infective Keratitis

A wide spectrum of ocular infections is associated with HIV infection. Viral keratitis is more common as compared to bacterial and fungal infections. In certain geographic areas, fungal keratitis has been reported to be an indirect indicator of HIV infection.<sup>23</sup> Recurrence is common for both varicella zoster virus keratitis and herpes simplex keratitis. Treatment for varicella zoster is with oral acyclovir 800 mg 5 times daily for 7–10 days or famciclovir 500 mg 3 times daily. Infection with herpes simplex virus requires half to one-fourth of the dose.

Microsporidia are obligate intracellular parasites known to cause gastroenteritis, sinusitis, and pneumonitis in HIV infected patients. Ocular involvement is in the form of a diffuse superficial punctate keratopathy associated with conjunctivitis.<sup>24</sup> Diagnosis is made by the characteristic staining of the intracellular organisms. Treatment is usually with topical fumagillin, pentamidine isethionate, and oral itraconazole or albendazole.

### Anterior Uveitis

Anterior uveitis is less common than posterior or panuveitis.<sup>25</sup> Drugs like cidofovir and rifabutin can also cause uveitis due to their toxicity.

### Ophthalmic Kaposi Sarcoma

Kaposi sarcoma most commonly involves the anterior segment of eye. Generally, ophthalmic Kaposi sarcoma is indolent. Ocular tumor growth can result in severe damage to the ocular adnexa and ocular surface. Involvement of the eyelids can cause significant disfigurement and lid dysfunction. Trichiasis can develop due to mechanical ectropion or entropion. Lagophthalmos and trichiasis can cause profound irritation, dryness, and infections leading to corneal scarring.<sup>26</sup>

Large lid tumors can also induce irregular corneal astigmatism. Conjunctival involvement may result in recurrent subconjunctival hemorrhages. Ultimately, vision could be lost due to lid

dysfunction, corneal surface changes or due to visual obstruction. The lesions are purplish-red to bright red and highly vascular with surrounding telangiectatic vessels. They may be macular, plaque-like or nodular.

DNA sequences of human herpes virus 8 (HHV 8) have been detected in Kaposi sarcoma in patients with and without HIV infection.<sup>27</sup> HHV 8 is considered to be quite uncommon in the Indian subcontinent. This could be the probable reason for the low prevalence of Kaposi sarcoma in AIDS patients in India. In a large series of 100 HIV positive cases from India, Kaposi sarcoma was not found in any.

## POSTERIOR SEGMENT LESIONS

Posterior segment lesions involve the retina, choroid or optic nerve. Sometimes, the lesions may involve more than one structure. More than 50% of the patients with ocular involvement have lesions in the posterior segment.<sup>12</sup> Some of these lesions can threaten vision but patients may even be asymptomatic. When the lesions do not involve the posterior pole, the usual symptoms include floaters, flashes of light, visual field defects, and dimness of vision. In India, as routine ophthalmic check-up is not a norm, in many instances patients are seen in an advanced stage. Posterior segment lesions are divided into the following categories.

### HIV Retinopathy

HIV related retinal microangiopathy was the most common ocular lesion in patients with AIDS before the introduction of highly active antiretroviral therapy (HAART). It was detected in almost 50% of the cases during the late stages of HIV infection.<sup>12</sup> Presently, due to the early treatment of HIV, the prevalence of retinopathy has declined.<sup>28</sup> HIV retinopathy is a noninfectious microvascular disorder characterized by cotton-wool spots, microaneurysms, retinal hemorrhages, telangiectatic vascular changes, and areas of capillary nonperfusion. Cotton-wool spots occur in approximately 25–50% of the patients with advanced HIV disease and are the earliest and most consistent findings in HIV retinopathy (Fig. 83.2). A cotton-wool spot is caused by a circulatory disturbance in a tiny area of the retina. Usually, the spots are distributed along the vascular arcades. The condition may mimic diabetic and hypertensive retinopathy. However, hard exudates observed in diabetic retinopathy are not present in HIV retinopathy. In addition, cotton-wool spots in HIV retinopathy are much smaller in size and persist for a shorter period. A patchy involvement of the retinal capillaries is seen in AIDS, in contrast to a widespread capillary disease seen in preproliferative and proliferative diabetic retinopathy. The average time for the disappearance of cotton-wool spots in HIV retinopathy is 6–12 weeks.<sup>29</sup> They are not vision threatening, although in advanced HIV disease they can produce small visual field defects. One can also distinguish cotton-wool spots from hypertensive retinopathy as the latter has vascular changes like arteriolar narrowing. In addition, they can be confused with early cytomegalovirus (CMV) retinitis lesions. Benign cotton-

**Fig. 83.2:** Showing cotton-wool spots along the retinal vessels in a HIV-positive patient.

wool spots can be differentiated by their smaller size, superficial location, lack of progression, and tendency to resolve over weeks to months. In HIV-seropositive patients, hemorrhages may involve both the nerve fiber layer and the deeper retina and may appear as flame-shaped, dot or blot hemorrhages. Telangiectatic vascular changes may be seen in patients with HIV disease and are often associated with microaneurysms.

### Opportunistic Infections

An increasing number of infections of the retina and choroid have been reported in individuals with advanced HIV disease. Although a number of these infections can also be seen in immunocompetent patients, it is important to remember that there may be significant differences in the clinical presentation in HIV-infected patients who present with lesser inflammation, take a longer time to respond to therapy, and have a higher chance of recurrence. Multiple foci of infection, bilateral infection as well as more than one infection in the same eye may occur in HIV-infected patients. Finally, new not yet described infections of the retina and choroid are likely to be encountered in HIV-seropositive patients in the future. A strong correlation exists between the level of immunosuppression (CD4+ cell count) and the appearance of opportunistic infections.<sup>30</sup>

### Cytomegalovirus (CMV) Retinitis

Cytomegalovirus is a species-specific DNA virus classified in the herpes group of viruses. CMV retinitis is the most common ocular infection in patients with HIV disease and occurs in 15–40%,<sup>31</sup> particularly when the CD4+ cell count is less than 100 cells/ $\mu$ L.<sup>32</sup> Earlier it was bilateral in 30–50% of patients; although that rate may now be lower as the administration of anti-CMV medication almost always prevents the onset of retinitis in the fellow eye.<sup>33</sup> CMV disease affecting the eye, however, tends to occur only in the developing foetus or in immunocompromised patients. CMV infection of the retina leads to the viral invasion of retinal cells with resultant retinal necrosis. The classic description of CMV retinitis

**Fig. 83.3:** CMV retinitis in AIDS patient.

is one of scattered yellow-white areas of necrotizing retinitis with a variable degree of hemorrhage and mild vitreous inflammation (Fig. 83.3). Indeed, some authors have described this as “cottage cheese with catsup” or “pizza pie” retinopathy. Initially presenting as small white, granular patches, these areas continue to enlarge if left untreated. Active lesions show a white retinal necrosis usually associated with hemorrhage. Often, the retinitis follows a perivascular distribution (Fig. 83.4). The advancing edge of these lesions is usually very sharp and spreads contiguously. Typically, over several weeks, untreated lesions progress to full-thickness necrosis with resultant retinal gliosis and pigment epithelial atrophy (Fig. 83.4).<sup>34</sup> The pathway of expanding lesions can be predicted by the appearance of venous sheathing or white dots distal to the leading edge, indicative of direct cell-to-cell spread of infection. Expanding lesions often take on a brushfire border, with the active edge of whitening spreading from the previously infected area. With involvement limited to the peripheral retina, patients either have no subjective complaints, or may complain of floaters. If retinitis begins in the posterior pole, the patient may notice a visual field deficit. The possible mechanisms for visual loss are

**Fig. 83.4:** Active CMV retinitis in AIDS patient.

**Fig. 83.5:** Tractional retinal detachment in a patient of CMV retinitis.

direct retinal necrosis by infection, optic nerve involvement and retinal detachment. CMV retinitis may result in either serous, rhegmatogenous, or tractional retinal detachment, although the latter is much more common (Fig. 83.5). Rhegmatogenous retinal detachment has been reported in 13.5–29% of patients with CMV retinitis and may occur during the active or healing phase of the disease.<sup>34</sup> These detachments are particularly difficult to repair using standard retinal detachment surgery. Other findings associated with CMV retinitis include perivasculitis, vascular attenuation and vessel closure, as well as vitritis, anterior uveitis, and papillitis (Fig. 83.6).

Approximately 6% of patients with CMV retinitis are estimated to have frosted branch angiitis,<sup>38</sup> an entity originally described by Ito et al.<sup>36</sup> It is essentially a severe form of vasculitis, which affects the entire retina. Although both arteries and veins are affected, venules tend to be affected more. Frosted branch angiitis may be an idiopathic disorder or can be associated with ocular and systemic diseases. AIDS retinitis and *Toxoplasma* chorioretinitis are the most frequent ocular associations, while systemic lupus erythematosus (SLE), Crohn disease, large cell lymphoma, and

**Fig. 83.6:** Healed CMV retinitis.

**Fig. 83.7:** Frosted branch angiitis.

acute lymphoblastic leukemia are the systemic disorders associated with frosted branch angiitis (Fig. 83.7).

### **Varicella Zoster Virus Disease**

**Acute Retinal Necrosis (ARN)** It has been described in otherwise healthy adults of either sex of any age, but is more common in immunocompromised individuals, including those with AIDS.<sup>11</sup> In a majority of the patients, the retinal necrosis syndrome appears to be caused by VZ virus, however, HSV has also been implicated as a causative agent.

Clinically, the syndrome is insidious in onset, with a mild anterior uveitis accompanied by blurred vision. However, sometimes ARN may present with severe ocular pain. Examination of patients during the early stage of this syndrome reveals evidence of posterior and anterior uveitis, keratic precipitates, vitreous cells, and clouding of the ocular media. The retinitis is often seen first in the peripheral fundus but within a matter of days to weeks, may progress to a dramatic whitening of the peripheral retina and retinal pigment epithelium in multifocal and coalescent patches. Vasculitis involving both arteries and veins is a prominent feature, usually associated with areas of hemorrhage and vascular occlusion. An acute swelling of the optic nerve head and macular edema are often present during the active phase of the disease. If the contralateral eye is also involved, the clinical course is similar.

The subsequent course is one of resolution of the retinal lesions with the regression of the retinal whitening, followed by mild pigmentary scarring of the retina with sharp demarcation between the normal and affected areas. Regression begins at the outer margin of the lesions and moves centrally, this may be quite rapid, taking only 2–3 weeks. A late sequela is the development of vitreoretinal traction due to organization of the vitreous. This traction leads to retinal tears, and rhegmatogenous retinal detachment. Clinical differentiation between the various HSV types and VZV is often not possible, however, there are indications that retinitis due to HSV-2 begins at the posterior pole.<sup>37</sup>

**Progressive Outer Retinal Necrosis (PORN)** It is a recently recognized variant of necrotizing herpetic retinopathy representing

a distinct form of ARN, developing in patients with AIDS or other immunosuppressive conditions.<sup>38</sup> It is characterized by early macular retinitis in the presence of little or no intraocular inflammation. There is rapid progression with the development of lesions in the mid and peripheral retina with no consistent direction of disease spread unlike that seen in cases of ARN. Unlike ARN and typical CMV retinitis, which involve the full thickness of the retina, this condition is characterized by deep retinal opacification without granular borders, giving the impression of an “outer retinitis.” With progression there is a clearing of the areas around the retinal vessels, which has been described as a “cracked mud” appearance. These areas are either regions of perivascular retinal sparing or this pattern may represent an early removal of necrotic debris and edema from retinal tissues adjacent to the vasculature (Fig. 83.8). As infected areas of the retina become necrotic, large retinal breaks occur leading to rhegmatogenous retinal detachment in a majority of the affected eyes, contributing to the overall poor prognosis. Diagnosis of PORN is always clinical, based on its characteristic appearance as described. However, it closely mimics ARN and CMV retinitis (Fig. 83.9).

### **Treatment of Viral Retinitis**

The treatment of viral retinitis may be systemic, local or a combination of the two. The following drugs are in use:

**Ganciclovir** It is a nucleoside analog that acts as a competitive inhibitor and faulty substrate for CMV DNA polymerase. Ganciclovir inhibits all herpes viruses, including CMV by preventing DNA elongation. An induction dose of 5 mg/kg every 12 hours for 14–21 days should be followed by a maintenance dose of 5 mg/kg/day, indefinitely.<sup>39</sup> It takes 2–3 weeks before the clinical effect is apparent and 3–6 weeks before complete healing is achieved. Since ganciclovir is virustatic, recurrence often occurs within 10–21 days of discontinuation of therapy. The major side effect is neutropenia (5%–40%), which can be managed with granulocyte colony stimulating factor (G-CSF) 300 µg daily. Other adverse effects include thrombocytopenia, anemia, nausea, vomiting, and elevated liver enzymes.

**Fig. 83.8:** Progressive outer retinal necrosis in AIDS patient.

**Fig. 83.9:** CMV retinitis involving posterior pole.

**Foscarnet** It is a pyrophosphate analog that inhibits DNA polymerase (of CMV and other herpes viruses HSV-1, HSV-2, VZV, and Epstein-Barr virus) and reverse transcriptase by directly affecting the pyrophosphate binding site. This agent is also virustatic and it has an intrinsic anti-HIV effect that may be beneficial in reducing the HIV viral load in combination with other antiretroviral agents. An induction dose of 90 mg/kg twice a day for 14–21 days is followed by a maintenance dose of 90–120 mg/kg/day indefinitely.<sup>40</sup> Cessation of retinal lesion advancement and resolution of the acute inflammation is usually seen within 4 weeks. The major side effects are nephrotoxicity and hypocalcemia, causing arrhythmias and seizures. Electrolyte imbalance leading to hypercalcemia and hyperphosphatemia or hypophosphatemia may occur.

A combination of foscarnet and ganciclovir is more effective than monotherapy in the treatment of recurrent or resistant viral retinitis.<sup>41</sup> Unfortunately, combination intravenous therapy necessitates multiple intravenous infusions daily and has a marked negative effect on patient's lifestyle.<sup>42</sup>

**Acyclovir** It is a nucleoside analog that has potent activity against HSV-1 and 2, and VZV. The recommended intravenous dose is 1500 mg/m<sup>2</sup>/day divided into 3 daily doses for 7–10 days. This should be followed by an oral therapy of 800 mg 5 times daily for VZV and 400 mg three times daily for HSV-1 and 2 for 14 weeks duration. Complete regression occurs within 4 weeks and chances of involvement of the fellow eye are also reduced with this therapy.

**Intravenous Cidofovir** It is a nucleotide analog, which does not require phosphorylation by viral encoded enzymes. It is active in uninfected cells, can act preemptively, and may retain activity against ganciclovir-resistant strains of CMV. An induction dose of 5 mg/kg intravenously every week for 2 weeks followed by a maintenance dose of 5 mg/kg every 2 weeks, indefinitely, is recommended.<sup>43</sup> Increased proteinuria and elevations in serum creatinine are the major dose limiting toxicities.<sup>44</sup> Ocular complications include transient iritis (up to 40% cases) and ocular hypotony (12% cases).<sup>45</sup> However, since decreased intraocular pressure is common and usually clinically insignificant in patients

with advanced AIDS, the clinical relevance of this finding is not clear.<sup>46</sup> The iritis responds well to topical steroids and cycloplegics.

**Ganciclovir Intraocular Implant** The ganciclovir implant is a sustained-release drug delivery device that contains about 4.5–6 mg of ganciclovir. A pellet of ganciclovir salt is first coated with a permeable layer of polyvinyl alcohol, followed by an impervious coating of ethylene vinyl acetate, and then by another coating of polyvinyl alcohol. It is placed into the vitreous cavity through a 5–6 mm incision in the pars plana and sutured to the sclera. The drug diffuses into the vitreous cavity by passive diffusion at the rate of 1 µg/hr over a 6–8-month period. After that, the device is usually surgically removed and replaced with a new device. The intravitreal levels attained by this drug are over twice those after intravenous administration, and this appears to be associated with a lower incidence of resistance and progression of retinitis. Adverse events include retinal detachments (12%), endophthalmitis (1.7%), and transient vitreous hemorrhage (7.8%). However, as with all local treatments, there is a risk of CMV disease in the fellow eye (up to 40% cases) and even extraocular CMV disease (10.3%).<sup>47</sup>

**Intravitreal Ganciclovir** Ganciclovir was the first anti-CMV compound administered as an intravitreal injection. The dose varies from 200–2000 mg/0.1 mL. These injections are given twice a week. They are usually tolerated well, are highly effective (Fig. 83.10), and relatively inexpensive. The main adverse effects include endophthalmitis, retinal detachment, and vitreous hemorrhage.<sup>48</sup>

### **Toxoplasma Retinochoroiditis**

*Toxoplasma gondii*, a protozoon, affects about 10% of the patients with AIDS. However, Toxoplasma retinochoroiditis is relatively rare and accounts for only 1% of AIDS related retinal infections.<sup>49</sup> It produces a necrotizing retinitis similar to CMV retinitis. Ocular toxoplasmosis is much less common in HIV infected patients than Toxoplasma encephalitis, probably due to difference in parasite load. There can be a single lesion or multifocal lesions in one or both eyes and broad areas of retinal

**Fig. 83.10:** Regression of CMV retinitis after intravitreal ganciclovir.

necrosis. The retina appears to have a hard and “indurated” appearance with sharply demarcated borders and small retinal hemorrhages. Progression is generally slow. CNS lesions are seen in 29–50% of HIV infected patients with ocular toxoplasmosis. Serologic diagnosis is often difficult due to a depressed antibody response.

### Mycobacterial Infection

Extrapulmonary and disseminated tuberculosis is seen more commonly in HIV positive patients. However, choroidal tuberculosis has not been so commonly reported. It is possible that many cases of choroidal tuberculosis remain asymptomatic and probably regress with the anti-tubercular treatment for extraocular tuberculosis. It usually presents as multifocal choroiditis with discrete yellow choroidal lesions mainly at the posterior pole. It may be associated with an exudative retinal detachment with variable vitreous inflammation.

Ocular tuberculous manifestations are the same as in immunocompetent patients. These patients require longer therapy because of their immunocompromised status and the inadequate absorption of drugs due to malabsorption associated with AIDS. Disseminated choroiditis is the most common manifestation reported.

Infection with atypical mycobacteria like *Mycobacterium avium-intracellulare* may occur in about 15–20% of the patients with AIDS. It has been demonstrated in choroid of the eyes removed at autopsy in about 1–6% of the patients. Both, *Pneumocystis jiroveci* and *M. avium-intracellulare* have also been demonstrated in the choroid of the same patient.<sup>50</sup>

**Ocular Tuberculosis** HIV/tuberculosis coinfection is of special concern especially in developing nations where background rates of TB are among the highest in the world. Ocular TB can present with protean manifestations, including choroiditis, choroidal granulomas (Fig. 83.11), chorioretinitis, endophthalmitis, subretinal abscess, and panophthalmitis.

Choroidal tuberculosis has not been found to be as common as systemic tuberculosis in patients with AIDS. No definite correlation of the occurrence of ocular tuberculosis with CD4 counts was found in our study, the largest series of patients with ocular TB in the world.<sup>51</sup>

### Fungal Infections

Candida and Cryptococcus are the most common intraocular fungal infections. Isolated candidal endophthalmitis is remarkably uncommon in contrast to systemic candidal infection in HIV-positive patients. Fluffy-white chorioretinal lesions along with snowball like masses are usually seen. Other lesions are creamy-white multiple chorioretinal lesions with an overlying vitreous inflammation.

*Cryptococcus neoformans* is the most common neurologic fungal infective agent in AIDS. It usually causes chronic meningitis, which may result in papilloedema, optic neuropathy, and cranial nerve palsy.

**Fig. 83.11:** Color fundus picture showing tuberculous subretinal abscess.

### Pneumocystis Jiroveci Choroidopathy

*Pneumocystis jiroveci*, a unicellular protozoan, is the most common opportunistic infection in patients with AIDS presenting as pneumonitis. *P. jiroveci* spreads to the choroidal layers through the hematogenous route. *P. jiroveci* choroidopathy is often seen in the patients treated with aerosolized pentamidine for PCP prophylaxis. It may be an initial sign of disseminated life threatening *P. jiroveci* infection.

Patients often do not have visual symptoms. The fundus shows multiple yellowish white, usually round, subretinal plaques distributed throughout the posterior poles. The lesions can coalesce on progression. Typically there is no vitreous inflammation. Fundus fluorescein angiography shows an early hypofluorescence of the lesions with delayed staining. Histopathologic studies of the eyes removed at autopsy revealed multiple eosinophilic, acellular, frothy, and vacuolated material. Special stains may demonstrate mature cysts of *P. jiroveci*.<sup>52</sup> *P. jiroveci* choroidopathy indicates a poor prognosis. Average survival after diagnosis is about 4 months.

## ORBITAL LESIONS

### Orbital Cellulitis

Aspergillosis and mucormycosis are the common orbital infections seen in patients with AIDS. Aspergillosis presents as a nongranulomatous disease with abscess formation and lack of fibrosis. This is in contrast to the slow granulomatous and fibrotic response in immunocompetent hosts. The classic presentation of orbital mucormycosis is severe unilateral headache, nasal stuffiness with granular or purulent discharge, facial or eyelid edema, fever, and leukocytosis.

## NEURO-OPHTHALMIC LESIONS

In advanced HIV disease, the brain is involved either by direct infection with HIV or with opportunistic infections. Neuro-ophthalmic complications occur in 10–15% of HIV-infected patients.<sup>53</sup> Since over 50% of the human brain is concerned in some way with the act of seeing, the eyes may show signs of brain

involvement. Blurred vision, problems with eye movement, or double vision may indicate some pathology in the brain. Nonviral infections are responsible for half of the CNS abnormalities; toxoplasmosis and cryptococcal infestation being the most common. Cryptococcal meningitis can present with papilloedema with peripapillary retinal hemorrhages,<sup>54</sup> optic atrophy, and ophthalmoplegia.<sup>55</sup>

## NEOPLASMS

Degradation of the immune system predisposes to specific malignancies like Kaposi sarcoma, non-Hodgkin lymphoma (NHL) and squamous cell carcinoma in HIV patients.

High-grade lymphoma is an AIDS defining disorder. Orbital and intraocular involvement is uncommon and is seen in less than 1%.<sup>56</sup> The clinical appearance of intraocular lymphoma is multifocal yellow-white chorioretinal lesions associated with vitritis. It may be associated with primary CNS lymphoma.

## Ocular Manifestations in HIV/AIDS in the Era of HAART

The advent of potent antiretrovirals has had a profound effect on the ophthalmological manifestations of patients with AIDS. As these drugs lead to an improvement in the immune function, patients have fewer opportunistic infections.<sup>12</sup> It has been estimated that the frequency of new CMV retinitis cases has decreased by 80% or more. Other HIV related ophthalmic disorders like Kaposi sarcoma are also seen infrequently. Those patients who have never received potent antiretroviral therapy, should be given a combination of agents in an attempt to improve immune function. In those with the evidence of immune reconstitution (elevated CD4+ T-lymphocyte counts, lower levels of HIV in the blood), control of CMV retinitis becomes easier and in many cases it is possible to discontinue specific anti-CMV therapy. Immune reconstitution may take 8 weeks or longer. Thus, aggressive anti-CMV therapy is required during this period. There are no well-established criteria to identify patients with sufficient immune recovery to allow the withdrawal of specific anti-CMV therapy.

An emerging problem among patients with CMV retinitis is “immune recovery uveitis.” As immune function improves following the initiation of potent antiretroviral therapy, some patients will develop heightened intraocular inflammatory responses, presumably to CMV antigens. Immune recovery uveitis is characterized by anterior chamber cells and a vitreous haze. Although the vitreous humor reaction may be transient, patients may be left with complications of inflammation, such as persistent macular edema, epiretinal membranes, and decreased vision.<sup>57,58</sup> Inflammation and macular edema respond to corticosteroid therapy, and possibly to nonsteroidal anti-inflammatory agents, but recovery of normal vision is rarely achieved in patients with macular edema. The frequency of immune recovery uveitis is not known, estimates range from 20% to 60%.

Patients with HIV can develop ocular manifestations at any point of their illness, so they need regular ophthalmological

examination. With the advent of HAART, the spectrum of ocular diseases (like opportunistic infections of other organ systems) is changing. Hopefully, these diseases will be more and more uncommon or less severe in the future.

### Summary

The incidence of ocular complications in HIV-infected individuals has decreased with the advent of highly active antiretroviral therapy (HAART). In spite of adequate and regular HAART, patients can still develop vision-threatening ocular lesions that can affect quality of life and hamper the ultimate goal of rehabilitation of the individual. Multiple pathogens found in the same individual or with an atypical presentation can give a clue to the diagnosis of the underlying HIV-related systemic disorder. Anterior segment and adnexal involvement in these patients may even be the primary presentation of AIDS.

Viral infections, such as herpes zoster, herpes simplex and molluscum contagiosum are more common. Patients with herpetic eye disease in AIDS may need long-term maintenance therapy. Herpes zoster ophthalmicus is seen relatively more commonly in India even in the HAART era.

Although the incidence of CMV retinitis has fallen with ART, it is still the most common ocular opportunistic infection. Other infections such as tuberculosis, toxoplasmosis, other herpes viruses and treponema can all cause damaging eye lesions.

Early identification and treatment of posterior segment manifestations is even more important as they can cause irreversible blindness.

Patients on HAART can develop severe inflammatory reaction due to immune reconstitution inflammatory syndrome (IRIS), which can cause severe ocular morbidity. With HAART newer manifestations of known lesions occur. Hence, it is important that ophthalmologists are aware of this new emerging phenomenon and treat them appropriately.

## Introduction

Sexually transmitted infections (STIs) are the most common infectious disease of public health importance. Each year there are an estimated 340 million new cases of curable STIs, as well as many millions of incurable viral STIs, including 5 million new human immunodeficiency virus (HIV) infection diagnosed globally (WHO). Over 30 different bacteria, viruses, and parasites are associated with STIs not only causing acute morbidity but also leading to chronic complications.

Most cases of HIV have been sexually transmitted. The link between STIs and the sexual spread of HIV is clear. STIs act as cofactors and facilitators for HIV transmission (epidemiological synergy).<sup>1</sup> The sexual HIV transmission is affected by a number of factors including the presence of an untreated STIs and the stage of HIV infection.

STIs occur frequently in HIV-infected persons but the management of STIs in these patients continues to challenge healthcare providers. Although these pathogens can cause a variety of easily recognized clinical syndromes, most are asymptomatic. For this reason, HIV-infected patients should be assessed for STI-related risk behaviors at every visit and screened annually for common STIs and more frequently if risk behaviors are reported. Both behavioral and biomedical interventions have a major role in protecting individuals from HIV and STIs. The prompt and appropriate treatment for STIs reduces individual risk of HIV infection. Since all STIs and HIV are preventable a high-quality STI programs are critical for controlling the transmission of HIV.

## STIs in HIV Infection

HIV alters the clinical presentation of STIs, their natural history, their relative prevalence and in some cases, their susceptibility to infection. HIV and STIs share common behavioral determinants; however the association is much more complicated. Genital ulcer diseases (GUD) and other STIs facilitates the sexual transmission of HIV. In both men and women STIs boost HIV shedding in the genital tract, which amplifies HIV infectiousness. The

presence of STIs also increases susceptibility to HIV by recruiting HIV-susceptible inflammatory cells to the genital tract as well as by disrupting mucosal barriers to infection. HIV infection also causes a rapid depletion of immune cells in semen. This immune depletion could render HIV-positive men more vulnerable to STIs, further increasing the risk of onward HIV transmission.<sup>2</sup>

Studies have estimated the overall risk for acquiring HIV in patients with STDs, and the odds ratio is: GUD 3.0–18, chlamydial urethritis 3.0–6.0, gonococcal urethritis 3.5–9.0, trichomoniasis 3, and genital herpes 2.<sup>1</sup> In a study done on a large cohort of patients attending STD clinic in Pune, India,<sup>3</sup> patients who had GUD were more than 4 times as likely to seroconvert as those without genital ulcers. For an HIV-negative person genital ulcer provides a portal of entry and for HIV-infected persons it provides a portal of exit. Presence of increased number of activated CD4+ cells in the ulcer further enhances the transmission or acquisition of HIV. Investigators in Kenya and the Ivory Coast found that HIV-1 RNA was significantly increased in cervicovaginal fluids of patients with STIs. Ghys et al.<sup>4</sup> noted a significant increase in detection of HIV-1 RNA in cervicovaginal secretions from patients with cervicovaginal ulcers. HIV-1 RNA decreased from 42% to 21% 1 week after treatment for STI, but no changes were observed in women whose STIs were not cured. The impact of nonulcerative STIs on the HIV epidemic could be potentially much greater because of high prevalence of nonulcerative STIs compared in most populations. While genital ulcers increase HIV transmission bidirectionally for both receptive and insertive sex partners, nonulcerative STIs like gonorrhea, chlamydial urethritis, or trichomoniasis increase risk primarily for the receptive partners.<sup>5</sup> Ho et al.<sup>6</sup> showed that *Chlamydia trachomatis* increases the replication of HIV-1, probably, through the generation of reactive oxygen products secreted by granulocytes. Chlamydial infection also causes secretion of cytokines that could affect the replication of HIV-1 and the number of receptive cells. Asymptomatic urethritis is independently associated with seminal HIV RNA shedding. Moss et al.<sup>7</sup> detected HIV-1 RNA in the urethra more frequently in patients with coexistent gonococcal urethritis than

in controls or in patients who had been treated. Cohen et al.<sup>8</sup> studied 86 HIV-seropositive patients with urethritis and found an 8-fold increase in secretion of HIV-1 RNA in semen when compared to a control group and the concentration of HIV-1 RNA in semen fell 2 weeks after appropriate antibiotic therapy to values not significantly different from those in controls.

Mostad et al.<sup>9</sup> noted a significant increase in detection of HIV-1 in samples from women with gonococcal cervicitis and vaginal candidiasis, but not in those with trichomoniasis or chlamydial infection. Increase in detection of HIV-1 RNA was also observed in pregnant women with cervical discharge. Increased HIV shedding is also seen in women with cervical ectropian, ranging from 15% with no cervical ectropian to 83% for with more than 50% ectropian.<sup>10</sup> STIs might increase the number of cells receptive to HIV-1. In addition to the increase in viral shedding an increase in CD4+ cells have also been demonstrated in genital secretions from women with STIs.<sup>11</sup>

## SYPHILIS

Since the emergence of the AIDS epidemic, syphilis has attracted renewed attention. The incidence of syphilis has also risen sharply in recent years mainly due to complacency among both MSM and heterosexuals regarding HIV infection, the ability to connect with sex partners online through Internet sites and the positive effects of antiretroviral therapy on quality of life.<sup>12</sup> The change in sexual behavior of HIV-infected persons such as seeking sex partners who are HIV-infected (serosorting) are also rising, further contributing to the epidemic.

The natural history of syphilis could be altered in the presence of HIV. Syphilis not only assumes unusual clinical presentations but also exhibit an unusual clinical course.<sup>13</sup> In coinfecting patients, syphilis may masquerade as other infections, including herpes and fungal infections and noninfectious dermatologic conditions.

Atypical presentations of early syphilis, early involvement of the central nervous system (CNS) and more frequent cases of neurosyphilis, rapid progression to tertiary syphilis, treatment failures and altered response to serological tests have been reported in coinfecting patients. Reactivation of syphilis is also seen in HIV-infected individuals with the possibility of relapse of secondary syphilis and subsequent transmission to sexual partners. However, despite the number of reports of unusual features, most HIV-infected patients present similarly to non-HIV-infected patients.

## Primary Syphilis

Primary chancre in HIV-infected patients may present as multiple chancres that are larger, deeper, and heal more slowly. Various morphological forms including gangrenous, phagedenic, and erosive are reported.<sup>14</sup> Primary chancre may still be present when lesions of secondary syphilis appear. This could be either due to rapid progression of the disease or delayed healing of primary lesion, or both.<sup>15</sup> Sometimes the tissue destruction caused by the chancre can be mistaken for donovanosis. Mixed infections with other STIs, mainly HSV, are not uncommon.

## Secondary Syphilis

Signs of secondary syphilis in HIV-infected patients may develop sooner. General symptoms like fever, headache, weakness, and ulcerative lesion (malignant syphilis) characterized by rupia like skin lesions are about 60 times more frequent in HIV-positive individuals than HIV-negative individuals.<sup>16</sup> Condyloma lata is also more common than in non-HIV-infected patients.

The rash can be more widespread and lasts longer. The simultaneous presence of all morphological lesions like papules, nodules, pustules, ulcers, and crusted forms is seen. Altered morphological forms such as palmoplantar keratoderma, livedo vasculitis of trunk, and vesicular and hyperkeratotic forms have also been described.<sup>17,18</sup> Clinical variants of secondary syphilis (corymbose, annular, nodular, or pustular forms) are also more frequently seen in HIV-seropositive patients.

Some clinical forms of secondary syphilis can mimic lupus vulgaris, leprosy, leishmaniasis, and pyoderma. Secondary syphilis should be considered in the differential diagnosis of inflammatory cutaneous disorders in HIV-positive individuals. The likelihood of unusual presentations in secondary syphilis is greater when CD4+ cell count falls below 150/mm<sup>3</sup>. CNS and ocular involvement are not uncommon in coinfecting patients. About 5% of patients of secondary syphilis develop uveitis,<sup>19</sup> which is bilateral in half of these cases. Orbital inflammation, conjunctival hyperemia, optic neuritis, chorioretinitis, and retinal vasculitis with retinal hemorrhage may also occur.

## Tertiary Syphilis

The ulcerative or nodular manifestations of benign tertiary syphilis are known as gummata. A gumma is thought to represent an enhanced immune response to *T. pallidum*, as organisms are present in low numbers in these lesions. Gumma arises either from reactivation of syphilis present in untreated or inadequately treated individuals, or from reinfection in previously sensitized individuals. There is evidence that *T. pallidum* persists in some patients who have received what is regarded as adequate therapy for syphilis. It has been suggested that *T. pallidum* persists in a state of commensality, with the potential to recover its virulence with immunosuppression. It may also be seen in immune-reconstitution syndrome associated with highly active antiretroviral therapy (HAART).<sup>20</sup> Gummatous lesions involving multiple organs including the brain may occur in HIV-infected patients<sup>21</sup> nevertheless syphilitic gumma remains uncommon in HIV-positive individuals.

Cardiovascular involvement may result in aneurysms, coronary artery stenosis, or aortic regurgitation. Although rare in antibiotic era rapidly evolving cases of syphilitic aortitis have been reported in HIV-infected patients.<sup>22</sup>

## Neurosyphilis

Concurrent HIV infection has a profound impact on neurological involvement in syphilis. Rapid progression of early syphilis to

neurosyphilis is also seen. HIV infection itself produces numerous neurological abnormalities. HIV impairs cellular immunity, macrophage function and peripheral CD4+ lymphocytes in these patients have decreased ability to assist B cells in the production of immunoglobulins. These functional immunological abnormalities will impair the host defence against syphilis and facilitate its progression. Meningeal inflammation induced either by HIV or syphilis will facilitate entry of either agent into the CNS.<sup>23</sup> Every patient with primary syphilis develops spirochetemia and is at risk of seeding the CNS and developing neurosyphilis. The immunological response of a patient has an important role in controlling the infection, even in presence of adequate antibiotic therapy.<sup>24</sup>

Neurologic manifestations of syphilis, including syphilitic meningitis, meningovascularitis, cranial nerve palsies, (second and eighth cranial nerves were most commonly involved) optic neuritis, myelitis, stroke and cerebral gummas are more common in HIV-infected patients.<sup>25–28</sup> Neurosyphilis should be distinguished from other opportunistic infections like CNS tuberculosis, cryptococcosis, or toxoplasmosis.

### Diagnosis of Neurosyphilis in HIV-Infected Patients

Routine CSF examination for HIV-infected patients with early syphilis is not recommended. Studies have shown that both a CD4+ cell count <350 cells/mm<sup>3</sup> and a serum RPR titer >1:8 are independent predictors of central nervous system invasion by *T. pallidum*.<sup>34</sup> Study by Marra et al. found an RPR serum antibody level ≥1:32 and a CD4 count <350 cells/mm<sup>3</sup> were more likely to have neurosyphilis. Therefore, most investigators recommend CSF examination for all HIV-infected patients with syphilis when serum RPR >1:32 or CD4 count <350 cells/mm<sup>3</sup> regardless of stage of syphilis. Following treatment the response of CSF parameters closely parallels that of decline in serum nontreponemal tests.<sup>35</sup> Therefore repeated CSF examination is not recommended unless RPR serum antibody levels remains ≥1:32. CSF VDRL is relatively insensitive (50%) for predicting neurosyphilis. FTA-ABS test has 100% sensitivity in ruling out neurosyphilis<sup>34</sup> and should be performed as part of the evaluation. However a positive test is not beneficial in diagnosing neurosyphilis. Therefore, any CSF abnormality, including pleocytosis >20 lymphocytes/mL or elevated protein levels should be considered diagnostic in the presence of reactive serum serology.

### Screening and Reporting

Serological screening is critical in diagnosing syphilis. Most guidelines recommend HIV-infected patients to be screened for syphilis at least once per year and for patients with continued high-risk behavior to be screened every 3 months.

Serologic test results for the majority of HIV-infected patients with syphilis are consistent with those seen in non-HIV-infected patients. However, seroreactivity may be delayed or absent,<sup>25</sup> and false-positive nontreponemal antibody tests (RPR/VDRL) has also been seen in HIV-infected patients. In one study, 4% of HIV-

infected patients tested had false-positive RPR.<sup>29</sup> Nontreponemal antibody levels may also decline more slowly after treatment than in HIV-non-infected patients.<sup>30–32</sup> Higher mean serum nontreponemal antibody levels are also reported<sup>34</sup> and prozone reaction occurs more commonly in HIV-infected patients.<sup>33</sup> No correlation has been found between serologic response to therapy and CD4 count.<sup>34</sup> In clinically suspicious cases with negative serological test, alternative tests such as biopsy of lesions or darkground microscopy could be helpful.

### Treatment and Follow-up (Table 84.1)

Due to lack of consistent data on either the frequency of failure or of progression to neurosyphilis and other complications, treatment for syphilis in HIV infected patients should be the same as non-HIV infected patients.<sup>36</sup> Treatment should be appropriate for the stage of the infection. The treatment of choice for all stages of syphilis is penicillin, which must be administered parenterally.<sup>37,39</sup> Azithromycin given as a single 2 g dose appeared effective in treating early syphilis<sup>40,41</sup> but studies have shown that *T. pallidum* develops resistance to this drug.<sup>42</sup> Benzathine penicillin does not reach effective levels against *T. pallidum* in the CSF, and relapses of syphilis with neurosyphilis are common in immunocompromised patients who were treated with a single dose of benzathine penicillin.<sup>16</sup>

Partners of patients with syphilis, regardless of whether they are coinfecting with HIV, should be examined and prophylactically

**Table 84.1** Syphilis Treatment

Treatment of early Syphilis
<ol style="list-style-type: none"> <li>1. Benzathine penicillin G 2.4 MU/IM single dose</li> <li>2. Procaine penicillin G 600,000 units/IM daily for 10 days</li> </ol>
Alternative regimen
<ol style="list-style-type: none"> <li>1. Doxycycline 100 mg/PO – bid for 14 days</li> <li>2. Azithromycin 2 g/PO stat</li> <li>3. Erythromycin 500 mg/PO qds for 14 days</li> <li>4. Ceftriaxone 500 mg/IM daily for 10 days</li> <li>5. Amoxicillin 500 mg/PO qds plus Probenecid 500 mg qds for 14 days</li> </ol>
Treatment of late latent, cardiovascular, and gummatous syphilis
<ol style="list-style-type: none"> <li>1. Benzathine penicillin G 2.4 MU/IM weekly for 2 weeks (3 doses)</li> <li>2. Procaine penicillin G 600,000 units/IM daily for 17 days</li> </ol>
Alternative regimen
<ol style="list-style-type: none"> <li>1. Doxycycline 100 mg/PO – bid for 28 days</li> <li>2. Amoxicillin 2 g/PO tid plus Probenecid 500 mg qds for 14 days</li> </ol>

Adapted from BASHH Clinical Effectiveness Group guidelines, May 2009.

treated with single dose benzathine penicillin G 2.4 million units IM. Treatment of partners will depend on the stage of the disease. Sexual transmission of *T. pallidum* occurs only when mucocutaneous syphilitic lesions are present. Since such lesions are uncommon after the first year of infection sexual partners beyond 1 year will not require treatment. For primary syphilis all partners for a period of 3 months plus duration of symptoms should be treated. Partners for 6 months plus duration of symptoms for secondary syphilis and 1 year for early latent syphilis should be treated.

## HERPES SIMPLEX VIRUSES

Herpes simplex virus (HSV) is the etiologic agent of genital herpes. Two serotypes, HSV-1 or HSV-2, are isolated from lesions caused by genital herpes. Classically genital herpes is caused by HSV-2, and orolabial herpes is caused by HSV-1. However, each serotype can cause disease in either location and increasingly HSV-1 has been isolated from genital lesions.<sup>43</sup> Majority of recurrent herpes outbreaks are caused by HSV-2. Serologic studies have documented HSV seropositivity in the overwhelming majority of HIV-infected patients (> 95% in some series).<sup>44,45</sup> A meta-analysis of 19 prospective observational studies reported that infection with HSV-2 increased risk of HIV acquisition 2.7-fold in men and 4.4-fold in women.<sup>46</sup>

HSV-2 infection increases the infectivity of HIV-infected persons by increasing the frequency and quantity of HIV shedding from genital mucosa even in asymptomatic infection. In HIV-uninfected persons the break in the epithelium caused by HSV increases the acquisition of HIV and increases the host susceptibility to HIV infection by upregulating the mucosal immune activity.<sup>47</sup>

## Pathogenesis

Laboratory studies have provided supportive evidence that HSV may be an important cofactor for HIV expression and transmission. In tissues coinfecting with HSV-1, HIV virions appear to be able to infect keratinocytes that lack CD4 receptors and are not usually vulnerable to HIV infection.<sup>48</sup> The HSV regulatory proteins ICP0 and ICP4 (infected cell protein no. 0 and 4) can upregulate the rate of HIV replication *in vitro*.<sup>49</sup> ICP0 and ICP4 transactivate the long terminal repeat (LTR) of HIV-1 and both ICP0 and ICP27 can upregulate HIV expression in CD4+ lymphoid cells. The transactivating protein of HSV, *Vp16*, acts synergistically with the HIV-1 Tat protein to increase HIV transcription from HIV-1 LTR.<sup>50</sup> Herpetic lesions are associated with infiltration of activated CD4 bearing lymphocytes, which may result in increased expression of HIV on mucosal surfaces. The rate of subclinical shedding of HSV is significantly increased in patients infected with HIV. The most common site of shedding is the perianal area. A CD4+ T-cell count <200/mm<sup>3</sup> has been associated with increased subclinical shedding of HSV in men with HIV infection. In a cross sectional study, HSV was isolated in 13% of HIV positive women as compared with only 3.6% of

HIV-seronegative women.<sup>51</sup> Severe episodes of anogenital herpes may be the first clinical signs of immunosuppression.<sup>52</sup> The chronic immunodeficiency brought upon by HIV puts patients at increased risk of HSV reactivation. Studies have demonstrated that acute or reactivated HSV infection may stimulate HIV replication.<sup>53</sup> HIV RNA levels in plasma significantly increased in patients with active herpes lesions. Ioannidis et al.<sup>54</sup> reported that long-term suppressive therapy with acyclovir may prolong survival in AIDS patients with history of severe HSV infections.

## Clinical Presentation

Anogenital disease caused by HSV in HIV-infected patients may vary from that in the non-HIV-infected populations in severity of initial infection or severity and frequency of recurrent infection. Increasingly acyclovir resistance is also encountered in the HIV-infected population. But majority HIV-infected patients with genital herpes present similarly to those in non-HIV-infected patients.

In advanced HIV disease, the lesions could be large, often hemorrhagic, deep, with raised margins simulating donovanosis, syphilis or giant chancroid. A small fraction has chronic persistent mucocutaneous ulceration, often involving large areas of skin in perianal, scrotal, and penile regions. Other atypical lesions seen are hyperkeratotic verrucous lesions and vegetating plaques. The verrucous lesions may closely mimic condyloma accuminata or verrucous carcinoma. Lesions of herpes simplex may acquire a zosteriform appearance.<sup>50</sup> Few patients present with an erythema multiforme like eruption. Ulcers may be coinfecting with other pathogens. Rarely patients with CD4 counts <100 cells/mm<sup>3</sup> may develop disseminated infection characterized by scattered, discrete, eroded, or crusted erythematous papules or papulovesicles. HSV is a common cause of proctitis in HIV-infected men who have sex with men (30% in some series). HSV associated encephalitis has also been reported.<sup>55</sup> Lesions caused by resistant virus may be atypical, more severe, larger, and slower to heal. Lesions of HSV presenting for longer than a month or the occurrence of HSV related pneumonitis, bronchitis or esophagitis in persons with HIV are considered AIDS defining.<sup>56</sup>

The immune response plays an important role in driving HSV into its initial latent state and in maintaining HSV latency.<sup>55</sup> The chronic immunodeficiency in HIV-infected patients increases risk for HSV reactivation and more frequent recurrences occur when CD4 counts is decreased to <100 cells/mm<sup>3</sup>.<sup>57</sup>

## Acyclovir-Resistant HSV

Acyclovir-resistant HSV occurs frequently in HIV infected and other immunocompromised patients. Risk factors for acyclovir resistance include a CD4+ cell count of less than 50/L and herpetic lesions of long duration.<sup>50</sup> In a study done by Safrin et al.<sup>58</sup> the median CD4+ cell count was 24 in 25 HIV-positive patients with acyclovir-resistant HSV. Acyclovir-resistant HSV should be suspected when HSV culture positive lesions persist despite adequate serum concentrations (>2 mcg/mL) of acyclovir.

Most resistant viral isolates are thymidine kinase (TK) deficient and are therefore resistant to acyclovir, valacyclovir, famciclovir, penciclovir, and ganciclovir. If suspected drug susceptibility testing could be carried out. Foscarnet an antiviral agent used to treat acyclovir-resistant HSV inhibits HSV specific DNA polymerase and does not require viral thymidine kinase for phosphorylation. It was observed that with discontinuation of acyclovir and initiation of treatment with foscarnet, a new isolate was recovered, characterized by loss of the acyclovir resistant trait and production of a functional thymidine-kinase enzyme.<sup>59</sup>

## Diagnosis

Diagnostic methods for genital herpes in HIV-infected patients are the same as those for non-HIV-infected patients. Diagnosis of typical genital herpes is usually made through clinical examination. HSV antigen detection including PCR, culture, Tzanck smear and biopsy are useful diagnostic tools. The culture in HSV detection is limited as the sensitivity decreases with the duration of the lesion. All atypical lesions should be confirmed by one of the diagnostic tests. Coinfection with another pathogen, such as syphilis, should be considered in atypical presentations. Serologic testing is of limited value in HIV-infected patients because most series show that the overwhelming majority of HIV-infected patients have antibody to HSV-1 and -2.

## Treatment

Acyclovir, valacyclovir, or famciclovir can be used to treat HSV. Possibility of antiviral resistance should consider in addition to nonadherence and poor absorption if herpetic lesions fail to heal with standard antiviral therapy. Intravenous therapy is necessary for severe mucocutaneous progressive disease, visceral involvement (e.g., oesophageal or hepatic), or antiviral resistance.

### Primary outbreak with uncomplicated presentation

- Acyclovir 400 mg PO tid
- or*
- Famciclovir 250 mg PO tid or 500 mg bid
- or*
- Valacyclovir 1g PO bid

### Reactivation and Chronic Suppressive Therapy

HSV-2 reactivation and viral HSV shedding has been shown to be higher in HIV coinfecting patients than in those who are seropositive for HSV alone,<sup>47,60</sup> indicating the increased risk of HSV transmission by HIV/HSV coinfecting patients.<sup>61</sup> Suppressive anti-HSV therapy has been shown to decrease frequency of recurrences and decrease but does not eliminate, viral HSV shedding and infectivity.<sup>62,63</sup> HSV reactivation is also associated with increased HIV RNA levels<sup>64</sup> and daily HSV antiviral therapy decreases HIV RNA levels to baseline in patients not receiving HAART.<sup>60,64</sup> This has resulted in the use of HSV suppressive therapy to be considered in HIV-infected patients who are not receiving effective ARV therapy.<sup>65</sup> Although

several studies have shown that acyclovir or valacyclovir reduce plasma and genital levels of HIV-1 in HSV-coinfecting patients,<sup>66</sup> two large studies of daily suppressive acyclovir therapy in HIV-uninfected adults among heterosexuals in Africa and MSM in Peru and the United States did not show a reduction in risk of HIV acquisition.<sup>67,68</sup>

### Chronic suppression

- Acyclovir 400–800 mg PO bid or tid
- or*
- Famciclovir 500 mg PO qd or bid
- or*
- Valacyclovir 1 g PO qd

### Treatment Options for Resistant HSV

An algorithm for treatment of ACV resistant HSV was developed at a round table symposium held in March 1993 by the CDC. This suggests:

- Increase the dose of oral acyclovir to 800 mg 5 times a day if new lesions continue to form after 3–5 days of treatment with standard dose.
- If there is no response after 5–7 days and lesions are accessible, the panel recommends addition of topical trifluridine every 8 hours until healing is complete. If lesions are not accessible, IV foscarnet 60 mg/kg twice a day or 40 mg/kg thrice a day until complete healing should be given.
- Foscarnet resistance has been reported and this may make cidofovir the most viable option.<sup>69</sup>
- Cidofovir—topical cidofovir gel 1%, applied to the lesions once daily for 5 days also might be effective.<sup>70</sup>
- Cidofovir 5 mg/kg IV q 2 weeks (limited experience).
- Immunotherapy—with interleukins.
- The use of topical imiquimod is still experimental.

## CHANCROID

Genital ulcers associated with chancroid potentiate the transmission of HIV. CD4 cells are plentiful in these ulcers and HIV can be isolated from HIV coinfecting chancroid ulcers. According to Cameron et al.,<sup>71</sup> men with chancroid are almost 5 times more likely to acquire HIV than those without GUD. HIV induced immunosuppression increases the clinical severity of *H. ducreyi* infection. The comparison of HIV seronegative with seropositive patients with chancroid has shown that seropositive patients have an increased number of genital ulcers than their seronegative counterparts.<sup>72</sup> Alternatively, HIV induced immunosuppression may reactivate genital herpes<sup>73</sup> and the coinfection of HSV with chancroid may explain the increased number of ulcers in such patients. Cases of chancroid with involvement of extragenital sites like digits and legs in association with the penile lesions have also been documented.<sup>74</sup> In advanced HIV disease, patients can present with complications like phimosis, phagedena, giant, multiple and destructive ulcers, which can be mistaken for donovanosis. HIV infection retards

the immune response of lymphocytes to *H. ducreyi* and delays the healing process. Delayed healing of genital ulcers of various etiologies has been reported in HIV-infected patients.<sup>74,75</sup> Delayed healing explains why the recommended single dose therapy with quinolones, ceftriaxone, and azithromycin has high failure rates in HIV-infected patients with chancroid.<sup>76</sup> Current CDC recommendations for treatment of chancroid in HIV-infected patient are the same as those for immunocompetent patients, though patients may require a longer duration of therapy with close follow-up.

### DONOVANOSIS

Donovanosis, being a genital ulcer disease, facilitates transmission of HIV. A few patients of coexisting donovanosis and HIV have been reported from South Africa and Brazil. There are very few reports about the altered clinical manifestations of donovanosis associated with HIV. Jamkhedkar et al.<sup>77</sup> compared the clinical features and response to treatment in genital lesions of donovanosis in both HIV seropositive and seronegative patients. They concluded that although genital ulcers at recruitment were not significantly large among HIV seropositives they took a longer time to completely heal (25.7 vs 16.8 days) and tended to produce greater tissue destruction. Increased incidence of squamous cell carcinoma has been reported in HIV seropositive young patients with donovanosis.<sup>78</sup> Etiological diagnosis is essential because genital ulcers due to HSV or syphilis may simulate donovanosis. The causative organism is difficult to culture and diagnosis requires visualization of dark-staining donovan bodies on tissue crush preparation or biopsy. Though treatment with erythromycin 500 mg 4 times a day for 14 days is quite effective treatment may need to be modified in patients with significant immunosuppression. In India, HIV-positive patients with donovanosis had a higher failure rate to first-line antibiotic therapy.<sup>79</sup> In Brazil, two AIDS patients with donovanosis failed to respond to conventional treatment with combinations of co-trimoxazole, tetracycline, and thiamphenicol. The role of oral azithromycin in the management of donovanosis in HIV-positive patients needs to be evaluated. CDC recommends injection gentamicin 1 mg/kg every 8 hours for such patients.<sup>56</sup> However, among HIV-seropositive pregnant women without significant immunosuppression, the clinical presentation and response to treatment in donovanosis appeared to be unaltered. In those patients, who do not respond, a biopsy is necessary to rule out malignancy.

### LYMPHOGRANULOMA VENEREUM (LGV)

Lymphogranuloma venereum (LGV) is a sexually transmitted infection (STI) caused by unique serovars of *Chlamydia trachomatis* (L1, L2, L3). No current evidence exists to support a difference in acquisition, natural history, or response to therapy of LGV in the setting of HIV coinfection. One retrospective study has shown that HIV appears to have no adverse effect on clinical features of LGV.<sup>80</sup> LGV should be considered in the

differential diagnosis of GUD, inguinal lymphadenopathy, or proctocolitis, especially in men who have sex with men. The CDC currently recommends that HIV care providers be alert for LGV in patients with rectal symptoms or proctitis. LGV proctitis can present not only with symptoms of classic sexually transmitted proctitis such as, bloody or purulent rectal discharge, tenesmus, pain on defecation but can also present in a more indolent fashion. Several diagnostic challenges can further confound one's ability to diagnose LGV. Diagnosis is based on clinical suspicion, epidemiologic information and the exclusion of other etiologies along with testing for *C. trachomatis* similar to non-HIV-infected patient. CDC recommends the same line of treatment for LGV as in HIV-negative patients; however, HIV-positive patients may require a longer course. Partners of patients with LGV who had sexual contact with the patient within 60 days prior to symptom onset should be examined and treated.

### NEISSERIA GONORRHOEAE AND CHLAMYDIA TRACHOMATIS

The incidence of concomitant gonorrhea and chlamydia is high among HIV-infected patients. Several studies have shown that infection with *N. gonorrhoeae* and/or *C. trachomatis* may increase both the risk of transmission and acquisition of HIV.<sup>81-83</sup> There are many reports showing statistically significant association of gonorrhea with HIV seroconversion<sup>4-8</sup> with risk estimates ranging from 3 to 5. In a study from Baltimore, the risk for female to male HIV transmission was doubled in gonorrhea patients.<sup>5</sup> All HIV-infected patients with ongoing high-risk sexual behaviors should be screened for gonorrhea and chlamydia at baseline and at least annually. There have been no formal studies evaluating differences in clinical presentation, diagnosis, or response to treatment of gonococcal or chlamydial infection in HIV-infected patients. There have been no reports of atypical presentations or failure of standard therapy in HIV-infected patients. Diagnostic tests and treatment recommendations are identical to those in non-HIV-infected patients.<sup>84</sup> There are also few anecdotal reports of increased recurrence of gonorrhea in HIV-infected individuals.<sup>85</sup>

### VAGINAL INFECTIONS IN HIV-INFECTED WOMEN

#### Trichomonas Vaginalis

Genital tract infection with *Trichomonas vaginalis* (TV) increases HIV shedding in the vaginal secretions of infected women and in the semen of infected men. Therefore, trichomoniasis plays an important role in HIV transmission. A nearly three-fold increase risk of HIV due to trichomoniasis was found in a recent study from sub-Saharan Africa.<sup>86</sup> In addition, successful treatment of trichomoniasis in HIV-infected women has been shown to reduce genital HIV shedding.<sup>87</sup> Clinical presentation, diagnosis, and treatment in HIV infected patient are identical to those in non-HIV-infected patients.

## Bacterial Vaginosis

Bacterial vaginosis, one of the commonest causes of vaginal discharge increases women's vulnerability to HIV infection.<sup>88</sup> An increased genital shedding of HIV has been observed in HIV-positive women with bacterial vaginosis. This increase in genital HIV shedding could be due to bacterial vaginosis caused changes in the genital immune cell population, most importantly an increase in CD4 cells with the CCR5 co-receptor, which are targets for HIV and could increase local HIV replication.<sup>89</sup> There are no difference in the clinical presentation, diagnosis, and treatment of bacterial vaginosis in HIV infected and non-HIV-infected patients.

## Genital Candidiasis

Vaginal candidiasis is increasingly reported in women with HIV.<sup>90</sup> The degree of immunosuppression plays an important role in HIV associated recurrent vulvovaginal candidiasis. Although majority of infection will response to intravaginal antifungal agents, with advance immunosuppression systemic antifungal therapy would be required.<sup>90</sup> Long term prophylactic therapy may be required in patients who are not on HAART.

## Molluscum Contagiosum (MC)

Two types of molluscum contagiosum viruses (MCV) MCV 1 and 2 have been identified. MCV 2 is common in adult men and patients with HIV infection.<sup>91</sup> 10–30% of patients with symptomatic HIV disease or AIDS have MC.<sup>92</sup> The prevalence and the severity of the disease increase with advancing immunodeficiency. Up to one third of patients with CD4+ T-cell counts of 100/mm<sup>3</sup> or lower will present with lesions.<sup>93</sup> Often molluscum in AIDS patients reflects the reactivation of latent MCV.<sup>94</sup> The individual lesions of MC may be quite large with a diameter of 10 mm or more (giant MC). The appearance of multiple lesions is more common than solitary papules and plaques. Sometimes the lesions may resemble comedones, abscesses, furuncles, condylomata, basal cell carcinomas, ecthyma, and cutaneous horns.<sup>95–98</sup> Lesions of MC are usually distributed over the face, including eyelids and ears, neck and in intertriginous areas like axilla, groin, or buttocks. In homosexual men, the lesions are often seen in the anogenital area, possibly related to sexual transmission. These lesions may have a varied morphology ranging from fine papular lesions to verrucous hypertrophic lesions and polypoidal masses. It is important to differentiate such lesions from keratoacanthoma, cryptococcosis, histoplasmosis, penicilliosis, and coccidioidomycosis, which are also common in HIV infected patients. Histological sections from HIV infected patients may show areas of acanthosis, hyperkeratosis, and nuclear atypia, which is hardly ever seen in HIV-seronegative individuals. Viral structures consistent with MC are present in the clinically uninvolved epidermis adjacent to the lesions of MC in some HIV infected patients. This may explain the large number of lesions seen in these patients and the difficulty in controlling the spread

and recurrences of MC lesions.<sup>99</sup> Treatment in HIV-seropositive patients is not very effective as new lesions frequently erupt.<sup>100</sup> Intralesional interferon alpha results in shrinkage of treated lesions but has no benefit on surrounding lesions.<sup>101</sup> Imiquimod deserves consideration.<sup>102</sup> Cidofovir, either by topical or intravenous route, may be effective in recalcitrant mollusca.<sup>103</sup> Clearance of MC is seen with HAART as the immunity improves. If HAART is commenced with low CD4 count (below 200/mm<sup>3</sup>) an increase in MC may be seen as part of immune reconstitution syndrome.

## GENITAL WARTS

Human papillomaviruses (HPV) are a large group of viruses that are capable of infecting squamous epithelia. About 30 different HPV types have a predilection for the anogenital tract and may cause asymptomatic infection, condylomata acuminata, squamous intraepithelial neoplasia, and rarely other anogenital carcinomas including cervical neoplasia in women. Patients can be infected with more than one HPV type and can be at risk for both dysplasia and benign disease. The prevalence of HPV in HIV-infected patients varies over time with the degree of immunosuppression.<sup>104</sup> HIV facilitates either the activation of recently acquired HPV infection or the reactivation of latent infection, or both.

HPV types 16 and 18 are responsible for the development of approximately 70% of cervical and anal dysplasia and cancer. HPV types 6 and 11 account for approximately 90% of benign genital warts.<sup>105</sup>

The presentation of HPV in HIV-positive patients ranges from condylomata acuminata (genital warts) to carcinoma. Various studies have shown an increased incidence of anogenital warts in HIV-seropositive individuals.<sup>106</sup> Kiviat et al.<sup>107</sup> demonstrated that HIV-seropositive men are 3.1 times more likely to be positive for HPV DNA by PCR than seronegative men and that the former often have infection with multiple subtypes of HPV compared with the latter (44% vs 23%). Critchlow et al.<sup>108</sup> also demonstrated that HIV seropositive asymptomatic men were 4.1 times more likely to have anal HPV DNA detected by PCR than seronegative men, and seropositive men with other constitutional, neurological or infectious diseases associated with HIV were 10.9 times more likely to have HPV detected from the anal canal.

The differentiation properties of perianal epithelium are different from epithelium of the penile shaft. These differences determine the expression pattern of HPV as the perianal epithelium shifts the HPV expression to the early genes. HIV infection might also activate HPV early genes in a tissue specific manner, favoring the perianal epithelium. Consequently perineum may mount lower immune response against HPV infections since it is more depleted in immune presenting cells, such as Langerhans cells, CD4+ T cells and macrophages. This local immunodeficiency may account for the higher rate of HPV occurrence in the perianal area than on the penile shaft.<sup>109</sup> HIV infected patients also have higher rates of cervical, anal, and other genital cancers. It is possible that HIV acts directly on

HPV. *In vitro* studies have shown that intracellular HIV-1 Tat mRNA can transactivate HPV type 16 E6 and E7, an action that is important in the development of squamous cell cancers. *In vitro* studies have also shown that extracellular HIV-1 Tat protein can enter HPV infected cells and upregulate HPV type 16 E6 and E7, and it also enhances E2 dependent HPV type 16 transcription. It is possible that extracellular Tat migrates from Langerhans cells or other HIV infected mononuclear cells to HPV infected epithelial cells and upregulate HPV.<sup>110</sup> Women with HIV infection appear to be at increased risk for HPV and related cervical intraepithelial neoplasia (CIN). Odd ratio for association between HIV and CIN has ranged from 10% to 14.7%.<sup>111</sup> The presence of HPV DNA, extent of disease and potential for the malignant transformation also appear to correlate with the degree of immunosuppression. Individuals with CD4+ cell counts less than 200/mm<sup>3</sup> are at the greatest risk.<sup>112</sup> Cervical cancer in an HIV-seropositive patient is an AIDS-defining illness.<sup>113</sup> Anal cancer is currently the fourth most common cancer among HIV-positive men,<sup>114</sup> and is about 7 times more common in homosexual men with HIV than those who are HIV seronegative and 40 times more common in homosexual men with AIDS.<sup>115</sup>

HIV infected patients have multiple lesions and even diffuse involvement of the anogenital areas.<sup>104</sup> They develop very large genital warts. On rare occasions, these become locally invasive and destructive (giant condylomas or Buschke-Lowenstein tumor). Although these tumors, are non metastasising,<sup>107</sup> they carry a significant risk of transformation into squamous cell carcinoma. CIN vulval (VIN) and anal intraepithelial neoplasia (AIN) have all been reported to occur more frequently in HIV-infected patients. Increased severity of HPV disease is seen with increased immunosuppression. They are more resistant to treatment, more likely to recur and develop anal and CIN with increased relative risk of developing in situ or invasive genital cancers.<sup>114–119</sup>

Diagnosis of external condylomata acuminata is usually made on clinical grounds. HPV should be considered in the differential diagnosis of anogenital symptoms, such as itching, bleeding, pain, or spotting after sexual intercourse. Patients with abnormal anogenital physical findings, such as, hypopigmented or hyperpigmented warty lesions, lesions that bleed, or any other lesions of uncertain etiology should be biopsied. Clinicians should maintain a low threshold to obtain biopsy of atypical lesions in HIV infected patients to excluded dysplastic changes or squamous cell cancer.

Examination of the anogenital area, including the vulva and vagina in women, should be made to assess for HPV lesions at baseline and as part of the annual physical examination in HIV infected patients. Cervical Pap smear should be carried out in all HIV-infected women at baseline, 6 months after baseline and then repeated annually, as long as results are normal. Anal cytology helps in the detection of precancerous dysplastic lesions or treatable early invasive disease. Pap smear of the anal canal are simple to perform and clinically effective<sup>120,121</sup> with comparable sensitivity and specificity to cervical cytology.<sup>122</sup> Similar to cervical

tissue, the anal epithelium at the dentate line has a transformation zone between squamous and columnar epithelia. This transition zone is subject to infection with and neoplastic transformation by HPV. Precancerous lesions of the anal squamous epithelium can develop and are classified according to identical Bethesda criteria and nomenclature developed for grading cervical lesions.<sup>123</sup> Anal cytology should be obtained at baseline and annually in HIV-infected men who have sex with men, patients with a history of anogenital condylomas and in women with abnormal cervical, vaginal, or vulval histology. Colposcopy should be performed in all HIV-infected women with any abnormal cervical cytology and anoscopy performed in all HIV-infected patients with abnormal anal cytology. Follow-up and treatment will depend on the abnormality. The use of HPV DNA testing can be a useful adjunct to Pap smears in non-HIV-infected women but it is not recommended in HIV-infected patients.

## Treatment

Treatment of genital wart in HIV-infected patients does not defer from those used in non-HIV-infected patients. However, HIV-infected patients have a much higher rate of recurrences.<sup>106</sup> Cryotherapy, podophyllotoxin, interferon, imiquimod, cidofovir gel, trichloroacetic acid (TCA), and bichloroacetic acid (BCA) have all been studied in small numbers of HIV-infected patients with mixed results. Some clinicians advocate treatment by excision and electrodesiccation because of the poor response and frequent recurrences after topical treatments.<sup>124</sup> Poor clearance rates are reported after therapy in HIV-infected patients with advanced immunosuppression. More than one method of treatment or longer duration of treatment is often needed. HPV vaccine should be offered to HIV-infected women between the ages of 9 and 26 years. Most of the data regarding HPV vaccine safety and efficacy are derived from studies in non-HIV-infected females. Studies are currently underway to provide more extensive data regarding the safety and efficacy of the vaccine in the HIV-infected population. HIV-infected women may have reduced antibody response to the immunization. Women who have been vaccinated with HPV vaccine should continue cytological surveillance as described above. There is currently are no recommendations to vaccinate males against HPV.

## HUMAN HERPES VIRUS-8

Human herpes virus-8 (HHV-8) was originally identified in Kaposi's sarcoma (KS) tissue from AIDS patients. HHV-8 is also associated with a rare type of non-Hodgkin's lymphoma (NHL), termed primary effusion lymphoma, and with the plasma cell variant of Castleman's disease. Furthermore, patients with HIV associated KS are at a significantly greater risk for the development of NHL than their unaffected counterparts. Although the biology of HHV-8 is not entirely understood, it appears to be a sexually transmitted infection in Western Europe and USA.

Most cases of AIDS associated KS have appeared in men who participated in homosexual activities or had a history of STIs.

Those persons who acquired HIV nonsexually (hemophiliacs or intravenous drugs abuser) have much lower rates of KS than those who contracted HIV from homosexual or bisexual contacts.<sup>125</sup>

Many studies have focused on shedding of HHV-8 in semen with variable results. Patients with KS appear to consistently shed HHV-8 virions in their oral secretions. Variety of lesions like patches, plaques, papules, nodules, and ulcers may appear anywhere on the skin or mucous membranes. Visceral involvement in KS, commonly affects the gastrointestinal tract, lymph nodes, and lungs associated with significant morbidity and mortality. In era of HAART, KS is seen much less commonly, suggesting that the development or resolution of KS is linked to immune system control of HHV-8.

### SCABIES

The clinical features of scabies in the HIV-positive patients are often determined by the degree of immunosuppression. As the immunity decreases ( $CD4^+$  cells  $<200/mm^3$ ), the more contagious and fulminant forms of scabies become apparent.<sup>126,127</sup> The unusual forms of scabies in HIV-seropositive patients can be divided into two overlapping categories, namely, papular and crusted (Norwegian or hyperkeratotic) forms. The papular forms are characterized by severely pruritic, generalized papules, topped by scabetic burrows, which may be scaly. The crusted forms are characterized by thick, friable, white-gray plaques, which may also be diffuse, but are commonly localized to scalp, face, back, buttocks, nails, and feet. The plaques are often associated with mild to severe fissuring. As the lesions become crusted, they tend to become less pruritic. Both forms may coexist. Scabies should be considered in any HIV-positive patient presenting with an atypical or pruritic rash. These patients may harbor thousands of scabies mites and they are highly contagious, as the shed crusts are loaded with mites. The crust can serve as food supply and protection: sustaining the mites for up to a week.<sup>128</sup> CDC treatment recommendations for treatment of scabies in HIV-infected patients are the same as for HIV-negative patients.

### HEPATITIS B VIRUS (HBV)

Majority of studies have shown that there is no increased risk for rapid development of AIDS or decline in  $CD4^+$  counts in hepatitis B virus (HBV) positive patients.<sup>129</sup> However, HIV infected individuals are at increased risk for acquisition of HBV and during acute HBV infection HIV-seropositive patients tend to develop more severe illness. They are also at increased risk for chronic HBV infection. Liver function profile of chronic carriers of HBV is less abnormal when they are coinfecting with HIV, perhaps reflecting less severe hepatic inflammation. Asymptomatic reactivation or reinfection with HBV appears to be relatively common among HIV infected persons, especially if they have marked immunosuppression. It is also observed that the response of HIV infected persons to vaccination against HBV is impaired. HEPATITIS C VIRUS (HCV) The rates of sexual transmission of hepatitis C virus (HCV) are

low among heterosexuals. Outbreaks of sexually acquired HCV infection have been reported, almost exclusively in MSM who reported sexual practices involving exposure to blood or even minimal trauma to the rectal mucosa.<sup>130</sup> Acute HCV infection should be considered in the differential diagnosis of transaminitis. HCV infection can hasten the progression of HIV and HIV infection can impair the response to treatment of HCV.

### CYTOMEGALOVIRUS (CMV)

Cytomegalovirus infection is common in AIDS. Patients with multiple partners are more likely to be infected with multiple strains of the virus. Several GI syndromes have been associated with CMV, including esophageal ulcers, esophagitis, gastritis, isolated intestinal ulcers, terminal ileitis, intestinal perforation, focal or diffuse colitis, hepatitis, pancreatitis, sclerosing cholangitis, and unexplained wasting. The key histopathologic feature is intranuclear and intracytoplasmic inclusions. Ganciclovir and foscarnet are effective.<sup>131</sup>

### SEXUALLY TRANSMITTED GASTROINTESTINAL PATHOGENS

Sexually transmitted gastrointestinal syndromes such as proctitis, proctocolitis, and enteritis occur in HIV infected patients similar to HIV-negative individuals. When outbreaks of gastrointestinal illness occur among men who have sex with men, sexual transmission should be considered. The gastrointestinal tract appears to be a major target organ in HIV infected patients, and all infections have a more aggressive course. Quinn et al.<sup>132</sup> have shown that 63% of HIV seropositive homosexual patients with anorectal diseases had more than one lesion at the time of presentation, and 20% had more than one pathogen identified. A wide variety of anorectal lesions have been described including ulcers, condylomas, fissures, fistula, and abscesses. Anorectal HSV in HIV infected patients tends to develop chronic progressive disease leading to large, destructive perianal ulcers. Rectal gonorrhea increases the risk of HIV acquisition 3-fold.<sup>133</sup>

Proctitis occurs predominantly among persons who participate in receptive anal intercourse. *Neisseria gonorrhoeae*, *Chlamydia trachomatis*, lymphogranuloma venereum (LGV), *Treponema pallidum*, and herpes simplex virus are the most common sexually transmitted pathogens. Proctocolitis is associated with symptoms of proctitis and diarrhea or abdominal cramps. Sexual transmission occurs via oral–anal contact. Causative organisms include *Campylobacter* sp., *Shigella* sp., *Entamoeba histolytica*, and rarely, LGV. CMV or other opportunistic agents might be involved in HIV-infected patients. Enteritis usually results in diarrhea and abdominal cramping without signs of proctitis or proctocolitis. It is also acquired by oral–anal contact. *Giardia lamblia* is the most frequently implicated organism in non-HIV-individuals. Studies evaluating the microbiology of HIV associated gastrointestinal diseases found cryptosporidiosis in 30%, Isospora in 10%, and *E. histolytica*, *G. lamblia*, Salmonella, and CMV in 5–10% of patients.<sup>134,135</sup> Multiple stool examinations might be necessary to diagnose these organisms. Blood culture

is advisable in suspected infectious diarrhea with fever in an HIV-infected patient.

Sexual transmission of enteric pathogens like *Shigella*, *Salmonella*, and *Campylobacter jejuni* is more common in homosexual men with AIDS. Also, the infections are more prolonged with frequent recurrences, bacteremia, and antibiotic resistance. Although there has been no documentation of sexual transmission of *Cryptosporidia*, *Isospora*, and *Microsporidium* which have been detected more frequently in patients with AIDS, this mode of transmission is suspected due to their relative high isolation rate in homosexual than in other categories of patients with HIV. Chronic severe *Isospora* and *Cryptosporidia* infection are associated with CD4+ cell count less than 100/L.<sup>136</sup> *Cryptosporidium* is the most widely recognized enteric pathogen with a worldwide distribution of 10% to 20% in patients with AIDS.<sup>137</sup> *Cryptosporidiosis*, which is usually chronic and protracted, is a cause of wasting syndrome or "slim disease". Protracted disease occurs despite the presence of antibody in stool, suggesting that antibodies do not help much. Patients with *cryptosporidiosis* may present with diffuse small intestinal disease, mild colonic involvement, ileocolitis, isolated ileitis, massive secretory diarrhea, pancreatitis, sclerosing cholangitis, or cholecystitis. *Cryptosporidiosis* can be diagnosed by stool examination or by intestinal aspirate. Treatment with spiramycin and paromomycin are effective. *Isospora belli* is a coccidium closely related to *Cryptosporidium*, with isolation rates ranging from 8% to 20% among African AIDS patients to only 0.2% among American patients with AIDS.<sup>138</sup> Symptoms are similar to *cryptosporidiosis*. Although sulfonamides are effective half of them relapse following treatment.

# Human Immunodeficiency Virus Infection in Women

Noreen A. Hynes • Jean Anderson • Adriana Andrade

# 85

## Introduction

The human immunodeficiency virus (HIV) pandemic has matured and evolved since the first cases of acquired immunodeficiency syndrome (AIDS) were noted in June 1981 among a cluster of men in Los Angeles, California, who reported having had sex with men.<sup>1</sup> Two distinct species of HIV exist, HIV type 1 (HIV-1) and HIV type 2 (HIV-2); HIV-1 is responsible for most infections globally and it is associated with more rapidly progressive disease than HIV-2 in untreated persons.<sup>2</sup> At the end of 2009 an estimated 33.3 million persons were living with HIV worldwide with heterosexual penile-vaginal intercourse accounting for most transmission of HIV-1.<sup>2</sup> Over time, there has been progressive feminization of the global pandemic with the proportion of affected women increasing steadily worldwide (Fig. 85.1) despite the most recent reported progress in reaching the target set in Millennium Development Goal 6 to halt and begin to reverse the spread of HIV/AIDS by 2015 (Table 85.1).

According to the World Health Organization (WHO), by the end of 2010 over one-half of all HIV infections worldwide

were among women.<sup>3</sup> The distribution of the estimated 18 million infected women is disproportionately concentrated in low-resource countries particularly sub-Saharan Africa (Fig. 85.2). For example, in the 9 most affected countries, all of which are in

sub-Saharan Africa, young women are between 4 and 13 times more likely to be infected with HIV compared with young men<sup>2</sup>. Approximately 4.7 million adults are living with HIV in Asia, 34% of whom are women.<sup>2</sup> The number of women living with HIV and AIDS in Asia varies greatly among different countries. In India, for example, it is estimated that 2.3 million adults are living with HIV of which 38% are women; heterosexual transmission was responsible for 90% of these cases.<sup>2</sup> A similar pattern is noted in other Asia-Pacific countries including Indonesia, Vietnam, and Pakistan.<sup>2</sup>

The overall distribution of HIV infections in high-resource countries, such as the USA, is concentrated in men-who-have-sex with men (MSM).<sup>4</sup> However, in the US, women and adolescent girls account for an increasing proportion of persons living with HIV and AIDS increasing from 7% in 1985 to 27% in 2007<sup>4</sup> (Fig. 85.3). Adolescent girls and young women ages 13 to 24 years

**Fig. 85.3:** Estimated rates of HIV infection among U.S. adults and adolescents, by gender and race/ethnicity 2008–37 states with confidential name-based HIV infection reporting. *Source:* Centers for Disease Control and Prevention. HIV Surveillance Report, 2008; Vol 20.

living with HIV, those from ethnic/racial minorities represent 83% of cases but only 27% of the overall age-matched female population.<sup>5</sup> Although HIV/AIDS is no longer among the 10 leading causes of death in the US, certain subgroups in the population bear a disproportionate burden of the disease. For example, in 2004, HIV was the leading cause of death among black women aged 25–34 years; the third leading cause of death among those aged 35–44 years; and the fourth leading cause of death among Latina women aged 35–44 years.<sup>6</sup>

## Transmission of HIV in Women

Worldwide, over 90% of HIV infections in adolescent females and women are due to heterosexual transmission.<sup>2</sup> However, in higher resource countries injection drug use (IDU) plays a more significant role in acquisition. For example, in the US, in 2008 approximately 20% of infections in women were via IDU.<sup>4</sup> Risk factors for transmission of HIV to women from their male sexual partners are complex and often interrelated and influenced by biological, social, and economic factors. Although commonly perceived to be more efficiently transmitted from women to men than vice versa, this remains an unresolved issue with conflicting outcomes from various studies. This is likely related to multiple factors that may simultaneously influence infectiousness and susceptibility as well as the differing quality of the studies. For example, some of the risk factors examined during these studies relied upon self-reported behaviors that are difficult to validate, adding increased uncertainty to statistical models.<sup>7,8</sup>

Risk factors for heterosexual acquisition of HIV in women have been well-documented. These include presence of genital ulcer disease,<sup>9,10</sup> other sexually transmitted infections in either the woman<sup>11,12</sup> or her partner,<sup>13,14</sup> other non-sexually transmitted genital<sup>15–17</sup> infections and other non-infectious causes of genital irritation or inflammation,<sup>18</sup> the stage of infection,<sup>19,20</sup> the HIV-infected partner's use of antiretrovirals (ART) and viral load,<sup>19,21–23</sup> type of sexual activity,<sup>24,25</sup> and mean age of the woman.<sup>26,27</sup> These risk factors for HIV acquisition are further enhanced by the high prevalence of non-consensual sex,<sup>28,29</sup> failure to use effective physical barrier methods,<sup>30,31</sup> uncircumcised HIV-infected male partner,<sup>32,33</sup> and the known or unknown high-risk behaviors of their partners.

Cohort studies conducted in the US have demonstrated an increased risk of heterosexual transmission to be associated with alcohol use,<sup>34</sup> history of childhood sexual abuse,<sup>35</sup> current domestic abuse,<sup>35</sup> and use of crack-cocaine.<sup>36,37</sup>

## Intimate Partner Violence in HIV/AIDS

High prevalence rates of HIV infection among women globally are inextricably intertwined with the perpetual pandemic of violence against girls and women.<sup>38</sup> This violence manifests itself in the home, the workplace, against sex workers, in conflict settings, and in trafficking of girls and women.<sup>39</sup> The intimate partner may perpetrate physical, sexual, and/or psychological violence (Table 85.2). Worldwide, 10–70% of women report

**Table 85.2:** Forms of Intimate Partner Violence (with Examples)

HIV/AIDS-Related Target	Progress to Date

Source: World Health Organization. Violence against women. [www.who.int/mediacentre/factsheets/fs239/en/](http://www.who.int/mediacentre/factsheets/fs239/en/). Accessed September 30, 2010.

physical abuse,<sup>40</sup> and 6–45% report sexual violence by an intimate partner at least once during their lives.<sup>28</sup> Furthermore, between 7% and 48% of females aged 10–24 years report that their first sexual encounter was coerced.<sup>41</sup>

Studies from both high- and low-resource countries have demonstrated statistically significant association with HIV acquisition among girls and women reporting intimate partner violence (IPV) compared with those women not reporting IPV.<sup>35,42,43</sup> Several mechanisms have been postulated to account for this observation, including (i) greater biological risk due to trauma of the vaginal, anal, or oral mucosa during coercive sexual contact,<sup>44,45</sup> (ii) increased sexual risk taking as an observed outcome of having experienced childhood sexual abuse, forced sexual initiation during adolescence, or ongoing IPV,<sup>35</sup> (iii) inability or limited ability to negotiate condom use due to a history or fear of IPV,<sup>38,46</sup> and (iv) lack of power or control in a partnership with age disparities, or with an intimate partner with ongoing risky behaviors for HIV acquisition, such as extramarital sexual liaisons or IDU.<sup>47,48</sup> Furthermore, violence or fear of violence should the woman's HIV infection state be discovered and/or revealed may lead to delayed diagnosis and/or treatment.<sup>46</sup>

Additional research is needed to test whether these demonstrated direct and indirect associations are causal. In the meantime, ongoing multi-sectoral approaches aimed at stemming both IPV and HIV/AIDS pandemics among women are in place. These include legal efforts to protect women, enhancing efforts aimed at the empowerment of women, and increasing both public awareness of the problems and providing education to prevent their occurrence.

## Clinical Signs and Symptoms of HIV Infection, AIDS and Associated Conditions in Women

Most manifestations of HIV infection are similar in women and men. Both may have non-specific symptoms in early HIV infection, including low-grade fevers, night sweats, fatigue, and weight loss. ART, as well as prevention and treatment and

prophylaxis of opportunistic infections (OI) appear to be similarly effective in women and men. Some conditions, however, occur with different frequencies in women and men. For example, HIV-infected men are eight times more likely than HIV-infected women to develop Kaposi sarcoma,<sup>49</sup> whereas in some studies, women had higher rates of herpes simplex infections<sup>50</sup> and bacterial pneumonia than men.<sup>51</sup> It is unclear if the differential rate of bacterial pneumonia is due to a gender-specific biological factor or to socio-cultural or socio-economic factors related to access to care as well as HIV-specific prevention and treatment modalities.

Women also suffer gender-specific manifestations of HIV disease, such as vaginal infections, pelvic inflammatory disease (PID), and human papillomavirus (HPV)-related cervical and other lower genital tract dysplasia. Many of the gynecological problems seen in HIV-infected women are the same as those experienced by HIV-uninfected women, with the former often experiencing more frequent or more severe infections, especially with greater immunosuppression. Vulvovaginal candidiasis is more frequent and more persistent and bacterial vaginosis is more persistent.<sup>52–55</sup> Large cohort studies have not shown significant differences in the prevalence of sexually transmitted causes of abnormal vaginal discharge, including gonorrhea, chlamydia, or trichomoniasis.<sup>56,57</sup> Human papillomavirus infections manifesting as either genital warts or cervical and other lower genital tract dysplasia, occur more frequently in HIV-infected women and are more likely to recur after treatment than in uninfected women.<sup>58–63</sup>

Herpes simplex virus (HSV) infections are more prevalent in HIV-infected than non HIV-infected women. Moreover, the frequency and severity of HSV genital ulcers as well as frequency of subclinical shedding are increased by HIV; although this is related to the level of immunosuppression, HIV-HSV co-infected women on ART, still have comparatively more genital ulcers and subclinical HSV shedding.<sup>64,65</sup>

PID appears to be more severe in HIV-infected women than in uninfected women and may be more likely to have tubo-ovarian abscesses or require more prolonged hospitalization,

but overall response to standard management is not affected by HIV status.<sup>66–68</sup> Although menstrual irregularities are often reported by HIV-infected women, data are conflicting as to the role of HIV or HIV-related immunosuppression in menstrual abnormalities<sup>69,70</sup> and there are numerous potential confounding factors, including drug and alcohol use, weight loss, and use of psychotropic medications.<sup>71</sup> Some studies have shown increased likelihood of prolonged amenorrhea and potentially earlier menopause.<sup>72–74</sup>

Idiopathic genital ulcers are a unique manifestation of HIV infection similar to aphthous ulcers.<sup>75</sup> These ulcers are generally seen with profound immunosuppression, and may co-exist with oro-esophageal ulcers or result in genital tract fistula formation. Genital ulcers can also be caused by cytomegalovirus (CMV) in the setting of severe immune compromise.<sup>76</sup> Women with ulcers that are persistent or worsening, have negative testing and do not respond to empiric treatment for more common causes of genital ulceration should have biopsy performed to rule out malignancy and to obtain appropriate immunohistochemical studies.

Finally, although initial studies reported lower levels of steady-state plasma viremia in HIV-1–infected women compared to their male counterparts, they failed to detect sex-associated differences in rates of disease progression. More recently a clinical trial showed that viral decay rates did not differ by sex.<sup>77</sup>

## HIV Diagnosis and Management

Early diagnosis of HIV infection is critical in the management of the HIV-infected woman in order to optimize quality of life, prolong survival, and prevent mother-to-child transmission through informed reproductive choices.<sup>78</sup> Ideally, all women should be encouraged to undergo HIV counseling and testing if they or their sexual partners have engaged in behaviors that put them at risk of infection. In the US, for example, the Centers for Disease Control and Prevention recommends HIV screening for all persons aged 19–64 years at least once as part of routine medical care and targeted screening for those with risk factors who are outside this age range.<sup>79</sup> The American College of Obstetrics and Gynecology recommends annual review of HIV risk factors and rescreening at least annually for women with known risk factors for HIV acquisition.<sup>80</sup> Knowledge of one's sero-status may result in earlier initiation of ART, if indicated, with subsequent immune reconstitution and longer survival and/or modification of sexual behaviors to decrease risk of transmission to uninfected partners.<sup>81,82</sup> Women whose HIV infections are detected early and receive appropriate treatment survive as long as HIV-infected men.<sup>83</sup> However, access to healthcare is suboptimal for many women at highest risk of HIV infection whether residing in high- or low-income countries.<sup>84,85</sup> Hence, possible warning signals of HIV infection such as recurrent vulvovaginal candidiasis or severe PID may not be heeded.

Guidelines for the treatment of HIV, including pregnant and lactating women, have been published.<sup>86–89</sup> Prolonged survival after HIV diagnosis is associated with treatment and follow-up by a healthcare provider with expertise in HIV.<sup>90,91</sup> Some of the

adverse effects associated with highly active antiretroviral therapy (HAART) are different in women than in men. Compared with men, women experience more frequent liver toxicity, especially with nevirapine when the CD4 T cell count is greater than 250 cells/ $\mu$ L,<sup>92</sup> dyslipidemia and fat maldistribution,<sup>93–95</sup> lactic acidosis,<sup>96</sup> and rashes.<sup>97–99</sup> These toxicities may be due to clinically significant gender differences in antiretroviral pharmacokinetics.<sup>100</sup> However, many of the studies examining these differences have been too small to be deemed representative, had only very limited pharmacokinetic data or utilized a retrospective study design. Long-term experience with some of the newer ARV agents is limited. However, certain general statements can be made. For example, efavirenz is the preferred non-nucleoside reverse transcriptase inhibitor in treatment-naïve patients. However, it is also a possible teratogen. Therefore efavirenz should be avoided in a pregnant woman during the first trimester or in a woman who desires to become pregnant or who does not or cannot use effective and consistent contraception.<sup>101</sup> Women taking ARV agents that have drug interactions with oral contraceptives should use an additional or alternative contraceptive method.<sup>87</sup> Gynecological conditions may present threats to health in the HIV-infected woman. HIV-infected women are at increased risk of infection with high-risk HPV serotypes and cervical intraepithelial neoplasia.<sup>60,61,102</sup> This risk is highest among women with CD4 T cell counts less than 200 cells/ $\mu$ L and a plasma viral load of greater than 100,000 copies/mL.<sup>63</sup> It is expected that an increased frequency of cervical dysplasia, greater severity with lower CD4 counts, and higher persistence or recurrence rates after treatment may result in increased risk for progression to invasive cervical cancer in HIV-infected women, if regular screening and treatment are not carried out. In the US it is recommended that HIV-infected women undergo a complete gynecologic evaluation, including assessment of cervical cell cytology for dysplastic or more severe changes, as part of their initial evaluation after HIV diagnosis, with another cytological evaluation 6 months later, and then annually if normal.<sup>80</sup> More frequent screening intervals are recommended for women with mild cytologic abnormalities, after excluding the presence of high-grade dysplasia with colposcopy and negative biopsies, and after treatment for dysplasia. Cytologic screening is generally unavailable to most women in low-resource settings; current and evolving screening strategies in these areas are focusing on alternatives such as visual inspection of the cervix after application of dilute acetic acid or the use of HPV testing.

HPV vaccines have been demonstrated to be safe and effective in HIV-uninfected adolescent females and women; clinical trials focused on clinical efficacy have not been carried out.<sup>103</sup> However, HIV infection is not a contraindication to their use. In many low-resource settings, the cost of the vaccine is currently prohibitive. Although the vaccines have been formulated based upon the most prevalent genotypes present in genital warts and/or cervical cancer in North America, Western Europe, and Australia, the oncogenic genotypes 16 and 18 are associated with about 80% of cervical cancers worldwide.<sup>104</sup>

## HIV in Pregnancy and Mother-to-Child Transmission (MTCT) of HIV

HIV infection during pregnancy is associated with a decline in the absolute CD4 T cell count, almost certainly due to hemodilution, since the CD4 percentage is largely unchanged. There appears to be no increased progression of HIV or increased incidence of HIV-associated opportunistic infections during pregnancy, as compared to HIV-infected non-pregnant women of similar HIV stage. However, HIV infection in women is associated with a 30% decrease in fertility,<sup>105</sup> low birth weight,<sup>106</sup> chorioamnionitis,<sup>107</sup> and a five-fold increase in maternal mortality.<sup>108</sup>

In 2008, an estimated 430,000 children were infected with HIV worldwide.<sup>109</sup> Almost all of these infections were acquired by MTCT. The exact mechanism of MTCT of HIV is unknown. Transmission may occur during intrauterine life, delivery, or breastfeeding. Risk of MTCT appears to be the greatest in the setting of advanced maternal HIV disease.<sup>110</sup> In general, there is a 15–30% risk of MTCT in untreated HIV, with the majority of transmission occurring late in pregnancy at the time of labor and delivery.<sup>111</sup> In low-resource countries where there are no safe and sustainable alternatives to breastfeeding, breastfeeding may account for as much as 40% of all MTCT without ARV prophylaxis. Increased risk of transmission is associated with higher maternal viral load<sup>112</sup>; co-infection with genital conditions that increase the genital tract viral load such as sexually transmitted and associated infections<sup>113,114</sup>; or other infections which increase maternal plasma viral load, such as malaria,<sup>115</sup> preterm birth,<sup>116</sup> prolonged membrane rupture,<sup>117</sup> and smoking<sup>118</sup>; or other substance abuse.<sup>119</sup> In high-resource countries, the risk of MTCT has been reduced to 1–2% or less by the application of targeted antenatal and postnatal prevention strategies.<sup>89</sup> These strategies include recommendations for universal screening for HIV in pregnancy leading to early identification of the HIV-infected pregnant woman,<sup>79</sup> subsequent initiation of ART if a woman needs it for maintenance of her own health or as prophylaxis for prevention of MTCT should she not yet meet indications for treatment,<sup>120,121</sup> elective Cesarean section when viral load is not fully suppressed,<sup>122</sup> and complete avoidance of breast feeding.<sup>123</sup>

The use of replacement feeding is the only way to eliminate MTCT via breast feeding but is only workable in settings where there is clean water, low deaths from diarrheal disease among breast feeding infants, and replacement feeding is affordable, available, and acceptable. Replacement feeding is unrealistic and unsafe in sub-Saharan Africa, for example, where over 90% of the global burden of new pediatric infections exists<sup>123</sup> and infant mortality due to diarrheal diseases is high.<sup>124</sup> In this setting, the focus has been on exclusive breast feeding (i.e., giving only breast milk without additional food or fluids) for the first 6 months of life, when HAART is not available, with weaning only when a nutritionally adequate and safe diet without breast milk can be provided.<sup>125–127</sup>

Data from observational and randomized controlled clinical trials have demonstrated HAART provided as prophylaxis to the breast feeding infant or lactating mother can significantly decrease post-natal HIV acquisition risk.<sup>128,129</sup> Pregnant and lactating women

who require treatment should initiate ART aimed at both decreasing maternal mortality and preventing MTCT of HIV. If the mother does not require treatment, it appears that ART prophylaxis given to the infant and triple-drug prophylaxis for the mother are both safe and effective strategies and are recommended for the duration of breast feeding.<sup>130</sup> Specific regimens for the prevention of MTCT of HIV among breastfed infants have been published,<sup>121,125</sup> and are also covered in detail in Chapter 86, “HIV in Children”.

### Summary

- The feminization of the HIV pandemic is growing with over 50% of cases now occurring in women.
- Over 90% of HIV infections in adolescent girls and women have been transmitted heterosexually.
- Intimate partner violence (IPV) is strongly associated with HIV acquisition.
- Fear of disclosure of HIV sero-status and subsequent IPV may result in delayed diagnosis and treatment.
- Gynecological conditions including PID and uterine cervical dysplasia appear to be worse in HIV-infected women than HIV-uninfected women.
- Side effect profiles for some antiretroviral agents are different in women than in men.
- In 2008, approximately 430,000 children were infected with HIV worldwide most of which occurred by MTCT at the end of pregnancy and during delivery.
- Use of ARV drugs in the mother and infant can decrease MTCT risk from 20–30% to less than 2%.
- Exclusive breastfeeding for the first 6 months of life when extended post-natal ARV infant therapy or safe and clean replacement feeding is unavailable can reduce the risk of MTCT during this period.

## HIV in Children

J. Lucey • C. Foster • T. Puthanakit  
• J. Ziegler • P. Palasanthiran

### Introduction

World Health Organization estimated in 2009 that 2.5 million children younger than 15 years were living with human immunodeficiency virus (HIV); 2.3 million of them in sub-Saharan Africa and that 370,000 new infections and 260,000 HIV-related deaths occurred in those younger than 15 years. Most of these children acquire HIV from their HIV-infected mothers *in utero*, at birth, or via breastfeeding. With successful interventions, the risk of mother-to-child HIV transmission can be reduced to less than 1%.<sup>1</sup> However, such interventions are still not widely accessible or available in most resource-limited countries where the burden of HIV is highest, and an estimated 1000 children become infected with HIV each day. Despite the number of children receiving antiretroviral therapy (ART) in low- and middle-income countries increasing from about 75,000 in 2005 to 275,500 in 2008, and to 360,000 in 2009; this equates to only 38% of the children who require therapy.<sup>2</sup> ART for infants and children living with HIV has changed dramatically from monotherapy in the 1990s to current use of combination regimens, typically highly active antiretroviral therapy (HAART).

ART in children has been shown to be effective in increasing survival, reducing opportunistic infections, and improving growth and neurocognitive functioning in all clinical settings whether resource-rich or -poor.<sup>3</sup>

As of February 2009, a total of 25 antiretroviral drugs have been approved for use in HIV-infected adults and adolescents; 16 of these have an approved pediatric treatment indication and are available as a pediatric formulation or capsule size (See Table 86.1).

### HIV and Breastfeeding

Prevention of mother-to-child transmission (MTCT) of HIV has been highly successful in well-resourced countries. However, MTCT continues to occur in under-resourced settings due to lack of funds for effective prevention programs. Transmission from breast milk remains a major mode of MTCT. The probability

of transmission of HIV through human breast milk is estimated at 0.00064 per liter of milk ingested and 0.00028 per day of breastfeeding.<sup>4</sup> A longer duration of breastfeeding is associated with an increased risk of HIV transmission. The monthly probability of late HIV transmission through breastfeeding after the age of 1 month is estimated to be 6.5–8.5 transmissions

**Table 86.1:** Pediatric Antiretroviral Drugs

Class	Drug name	Pediatric formulation
<b>Non-nucleoside reverse transcriptase inhibitors (NNRTI)</b>	Nevirapine (NVP)	S, ST
	Efavirenz (EFZ) ≥3 yrs	C, T, S
	Etravirine (ETR)	Not yet licensed in children
<b>Nucleoside/nucleotide reverse transcriptase inhibitors (NRTI/NTRTI)</b>	Abacavir (ABC) ≥3 mo	S, ST
	Didanosine (ddI)	P, C
	Emtricitabine (FTC)	S, C
	Lamivudine (3TC)	S, ST
	Stavudine (d4T)	C, P
	Tenofovir (TDF) >12 yrs only	T
	Zidovudine (AZT)	S, ST, C, IV
<b>Integrase inhibitor</b>	Raltegravir (RGV)	Not yet licensed in children
<b>Protease inhibitors (PI)</b>	Atazanavir (ATV) ≥6 yr with RTV boosting	C
	Darunavir (DRV) ≥6 yr with RTV boosting	T
	Fosamprenavir (FOS-APV) ≥2 yr	S, T
	Lopinavir/Ritonavir (LPV/RTV)	S, T
	Nelfinavir (NFV) ≥2 yr	P, T
	Ritonavir (RTV) >1 mo	S, C, T
	Saquinavir (SQV)	Not licensed in children
	Tipranavir (TPV) ≥2 yr with RTV boosting	C, S
<b>Fusion inhibitor</b>	Enfuvirtide (T-20) (≥6 yr)	I
<b>Entry inhibitor</b>	Maraviroc (MVC)	Not yet licensed in children
<b>CCR5 antagonist</b>		

Abbreviations: C, capsule; S, oral solution/suspension; ST, scored tablet; T, Tablet; P, powder for oral solution; I, Injectable; IV, intravenous.

per 1000 exposed infants.<sup>5</sup> A randomized clinical trial from Kenya demonstrated HIV transmission through breastfeeding and prevention of such transmission with formula feeding (36.7% and 20.5%, respectively).<sup>6</sup>

For women with known HIV infection living in well-resourced settings, the best approach to prevent postnatal transmission is to avoid breastfeeding. This approach is not feasible or safe for most HIV-infected women in resource-poor settings because of cost, unsafe water supply, and stigma associated with not breastfeeding. Depriving the infant of essential nutrition and immunologic defenses found in breast milk places the infant in a resource-poor setting at increased risk of mortality with a 2.6–5.8 fold increase in the first 6 months and, 1.4–1.8 fold increased risk of mortality in the second 6 months of life associated with formula feeding.<sup>7</sup> If complete avoidance of breastfeeding is not feasible, exclusive breastfeeding where the baby receives only breast milk for the first 6 months of life significantly reduces MTCT.<sup>8</sup> Additionally, early weaning from breast milk (e.g., at 6 months of age), if feasible, would limit the duration of exposure to HIV-infected breast milk thus preventing more than 85% of transmission due to breastfeeding while allowing the child to experience the early benefits of breastfeeding.<sup>9</sup>

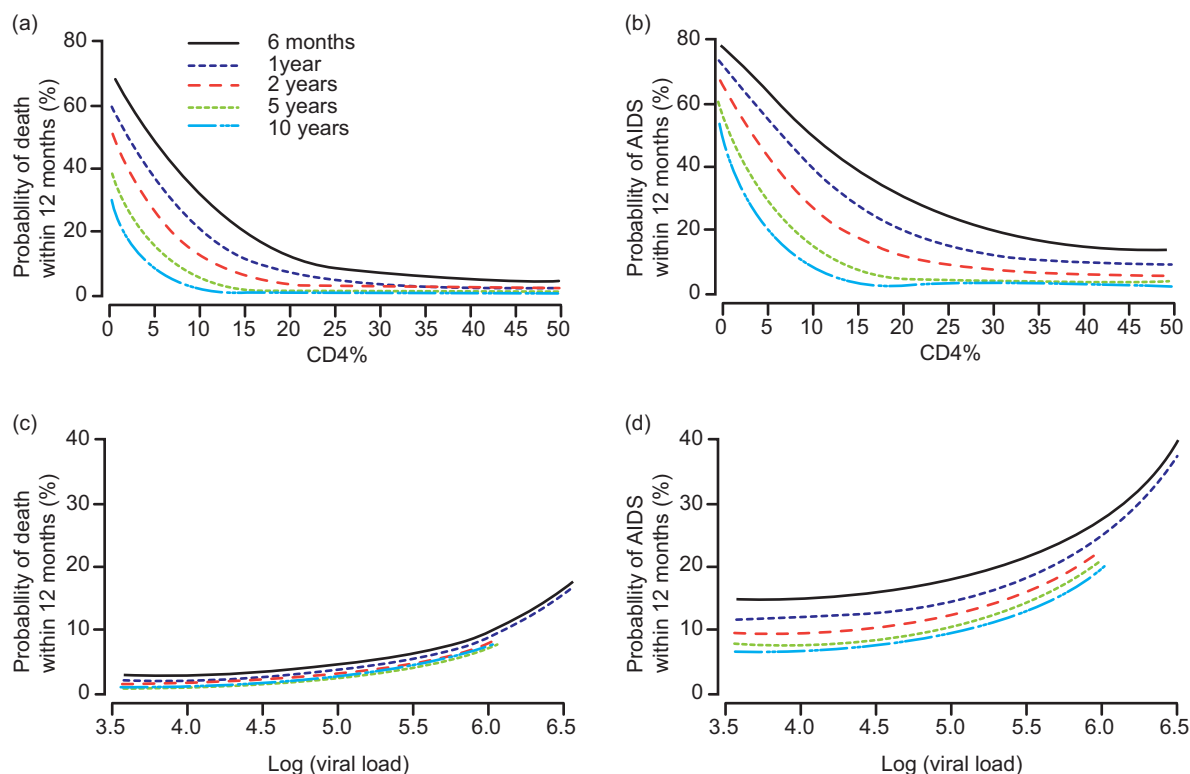

Studies examining intervention strategies to make breastfeeding safer in HIV-infected women have been conducted. Prolonged use of antiretroviral prophylaxis to either the mother or the infant can substantially reduce the rate of MTCT in a breastfed population. In the Kisumu breastfeeding study, ART was given to breastfeeding women from 34 weeks gestation until 6 months postpartum. Infants received single-dose nevirapine (NVP) at birth. The overall rate of transmission in infants was 3.9% at 6 weeks, 5.0% and 5.9% at 6 and 12 months postpartum, respectively.<sup>10</sup> In Malawi, the role of infant prophylaxis during breastfeeding was explored in the NVAZ trial with infants randomized to either single-dose NVP or single-dose NVP plus zidovudine for 1 week with prolonged breastfeeding. At 6–8 weeks, in babies who were HIV negative at birth, 34 (7.7%) babies who had NVP and zidovudine and 51 (12.1%) who received only NVP were subsequently found to be infected ( $p = 0.03$ ). In the PEPI trial where infants were randomly assigned to one of three regimens: single-dose NVP plus one week of zidovudine (control regimen) or the control regimen plus daily extended prophylaxis either with NVP (extended NVP), or with NVP plus zidovudine (extended dual prophylaxis) until the age of 14 weeks with cessation of breastfeeding at 6 months.<sup>11</sup> At 9 months, the estimated rate of HIV-1 infection (the primary end point) was 10.6% in the control group, as compared with 5.2% in the extended-NVP group ( $p < 0.001$ ) and 6.4% in the extended-dual-prophylaxis group ( $p = 0.002$ ). These trials provided evidence that interventions such as maternal and infant antiretroviral prophylaxis, to allow breast feeding during the critical first 6 months of life, followed by early weaning after the intervention is stopped can reduce HIV MTCT. Kafulafula et al. compared mortality outcomes from the various arms of both trials and found that HIV-uninfected infants in the PEPI trial were at significantly increased risk of serious gastroenteritis-related hospitalization and mortality

when compared with HIV-uninfected infants in the NVAZ trial where breastfeeding was prolonged.<sup>12</sup> There is accumulating data from other African nations that the reduction in postnatal HIV transmission that might be expected by early weaning may be countered by increases in serious gastroenteritis-associated morbidity and mortality associated with early cessation of breastfeeding. In Kuhn's Zambian study, one-half of the cohort was randomized to wean abruptly at 4 months while the other was randomized to continue breast-feeding. Weaning during the interval encouraged by the protocol (4–5 months of age) was associated with a 2-fold increased risk of mortality, 6–11 months of age was associated with a 3.5-fold increase, and weaning at 12–18 months of age was associated with a 4.2-fold increase when compared to prolonged breastfeeding.<sup>13</sup> Shortening the normal duration of breast-feeding for uninfected children born to HIV-infected mothers living in low-resource settings is associated with significant increases in mortality extending into the second year of life.<sup>13</sup> Intensive nutritional and counseling interventions reduce but do not eliminate this excess mortality. Heat-treated expressed breast milk is no longer considered a main feeding option in under-resourced settings. The 2010 WHO infant feeding guidance document states that heat-treating expressed breast milk of HIV infected mothers may be considered an interim feeding strategy in some circumstances.<sup>14</sup>

## Natural History of HIV in Children

The impact of effective ART in HIV-infected children is well established. Infants in particular have a higher short-term risk of disease progression and mortality than older children and adults. In the pre-ART era, 20% of infants in industrialized countries developed AIDS and 10% died within the first year of life. The remainder had a 4.7% per annum progression to AIDS or death. At 6 years, 75% of infected children were still alive with around half being alive at 10 years of age.<sup>15</sup> With the introduction of ART, a reduction in mortality in children by 70–80% has been shown in many cohorts.<sup>16</sup> Typical early signs of HIV include lymphadenopathy, candidiasis, chronic parotitis, hepatomegaly, splenomegaly, failure to thrive and developmental delay. Common opportunistic infections (OIs) include *Pneumocystis jiroveci* pneumonia, fungal infections, bacterial infections (especially with encapsulated organisms), mycobacterial infections and recurrent herpes zoster. In infants who acquire HIV perinatally, the mean plasma HIV RNA level in the first year of life is 185,000 copies/mL, significantly higher than in adults, while rapid progression and death is predicted by plasma HIV RNA greater than 299,000 copies/mL. Regardless of plasma HIV RNA level, a CD4 cell count of less than 15% is highly predictive of disease progression and death.<sup>16,17</sup> For children up to 12 years of age, a risk calculator estimating the 12-month risks of progression to AIDS and death, based on the patient's age and one of the following markers: CD4 percent, CD4 count, total lymphocyte count, or viral load can be found on the HPPMCS (The HIV Paediatric Prognostic Markers Collaborative Study) website.<sup>18</sup>

**Fig. 86.1:** Meta-analysis of data from 3941 European and American children (HPPMCS) prior to highly active antiretroviral therapy. The estimated probabilities of death within 12 months by selected age and CD4 percentage (a) and viral load (c) and the estimated probabilities of AIDS by selected age and CD4 percentage (b) and viral load (d) are shown. (Reproduced with permission from Elsevier, Dunn D. *Lancet* 2003;362:1605–11).<sup>19</sup>

Use of combination therapy after 1996/97 has resulted in significant reduction in mortality and morbidity in both adults and children. De Martino et al. evaluated the effectiveness of combination therapy on survival among 1142 children with HIV from 106 Italian centers and showed over 30% reduction in risk of death in the period 1996–98 when dual therapy became widespread.<sup>16</sup> A meta-analysis of survival data from 3941 European and American children, pre-ART, gives risks of disease progression or death at different ages according to presenting CD4 count or viral load, the former being the stronger predictor (Fig. 86.1).<sup>19</sup> CHER data reported a 75% reduction in mortality in those infants who started ART before symptoms or CD4 decline, with a rapid decrease in CD4 values, rapid disease progression, and sudden death all evident among infants in the deferred-therapy group.<sup>20</sup> A decrease in mortality rate by 80–93% in the post-ART era has been observed in the UK, hospitalization rates decreased by 80%.<sup>21</sup>

## Management of Infected Children: General Pediatric Considerations

Special considerations in management of HIV-infected children include:

- Diagnosis
- Age-specific differences in CD4 T cell counts
- Changes in pharmacokinetic parameters with age

- Differences in clinical and virological manifestations
- Immunization issues
- Adherence issues
- Availability of pediatric formulations

Healthy young children have higher CD4+ cell counts than adults which slowly decline to adult levels by about the age of six years, thus age-appropriate CD4+ counts should be used.

Decisions regarding management of HIV in infants and young children have often been based on percent rather than absolute CD4 counts because CD4 % is not age dependent. A recent study by Dunn et al., however, suggested that CD4 % had little or no prognostic value over and above absolute CD4 cell count, irrespective of age.<sup>22</sup>

Infants in particular differ from adults in body composition, renal excretion and liver metabolism causing substantial differences in drug distribution and clearance. Antiretroviral dosing is dependent on weight and body surface area and maintaining ART dosing accuracy in line with rapid growth in early childhood can be challenging, with high levels of under dosing reported.<sup>23</sup>

Standard childhood vaccination schedules should be followed with the exception of BCG which should not routinely be given to HIV-infected children due to the risk of disseminated BCG infection. MMR vaccine is routinely administered to HIV-infected children at 12 months unless they have severely impaired immunity. Influenza vaccine is recommended even in symptomatic HIV-infected children.

## Diagnosis of HIV Infection in Infants and Children

### CHILDREN <18 MONTHS

HIV-DNA PCR is currently the diagnostic method of choice for perinatally exposed children under 18 months of age. Umbilical cord specimens should not be used as contamination by maternal blood can occur. Sensitivity is less than 40% at less than 48 hours of age, and increases to greater than 90% by 2–4 weeks of age.<sup>24</sup> A positive DNA PCR must be confirmed by a second virological test obtained from a separate sample taken more than four weeks after birth.

For infants followed up from birth, US guidelines recommend testing within 48 hours of birth, at 14–21 days of age, 1–2 months, and again at 4–6 months. WHO has recommended HIV-1 DNA or RNA testing within the first 14 days of life, at 1–2 months of age, and again at 3–6 months of age.

Breast fed infants cannot be shown to be HIV uninfected until at least one month after weaning.

### CHILDREN >18 MONTHS

HIV diagnosis requires positive HIV-1 antibody detection tests—positive ELISA and confirmatory test (Western blot or immunofluorescence) (Table 86.2).

## When to Initiate Therapy in Antiretroviral-Naïve Children

Some useful guidelines for the use of antiretroviral agents in pediatric HIV infections are available (see Box 86.1). The current recommendations for initiation of treatment designate four age groups—infants, children aged 1 to younger than 3 years, children aged 3–5 years, and children aged >5 years (Table 86.3).

### Box 86.1 Useful Guidelines of HIV Management in Children

**US guidelines** can be accessed via <http://aidsinfo.nih.gov/Guidelines/GuidelineDetail.aspx?guidelineID=8&ClassID=1>

**International readers** should refer to WHO; <http://www.who.int/hiv/pub/paediatric/infants2010/en/index.html>

**Paediatric European Network for Treatment (PENTA)**  
[http://www.pentatrials.org/HIV\\_759.pdf](http://www.pentatrials.org/HIV_759.pdf)

**Table 86.2:** WHO Case Definition for HIV Infection\*

#### Adults and children 18 months or older

HIV infection is diagnosed based on:

- Positive HIV antibody testing (rapid or laboratory-based enzyme immunoassay) and confirmed by a second HIV antibody test (rapid or laboratory-based enzyme immunoassay) relying on different antigens or of different operating characteristics

and/or;

- Positive virological test for HIV or its components (HIV-RNA or HIV-DNA or ultrasensitive HIV p24 antigen) confirmed by a second virological test obtained from a separate determination

#### Children younger than 18 months:

HIV infection is diagnosed based on:

- Positive virological test for HIV or its components (HIV-RNA or HIV-DNA or ultrasensitive HIV p24 antigen) confirmed by a second virological test obtained from a separate determination taken more than four weeks after birth
- Positive HIV antibody testing is not recommended for definitive or confirmatory diagnosis of HIV infection in children until 18 months of age

\*Referenced from 2006, WHO Case Definitions of HIV Surveillance and Revised Clinical Staging and Immunological Classification of HIV-Related disease in adults and children. Available at: <http://www.who.int/hiv/pub/guidelines/HIVstaging150307.pdf>.

### CHILDREN <12 MONTHS

Risk of disease progression is inversely correlated with age in younger HIV-infected children.

The CHER trial randomized infants born to known HIV positive mothers either to start ART at diagnosis (within 12 weeks) or after development of symptoms, or fall in CD4 count. CHER demonstrated a 75% reduced mortality in infants who started ART before symptoms or CD4 decline.<sup>20</sup> More recently, the WHO has recommended that this be extended to all children diagnosed before their second birthday, although European and US guidelines remain as yet unchanged.<sup>25</sup>

### SYMPTOMATIC CHILDREN AGED >1 YEAR

Antiretroviral therapy should be started in all children aged 12 months or older with CDC clinical stage B or C disease or WHO stage 3 or 4 (Tables 86.4 and 86.5) regardless of CD4

**Table 86.3:** Comparison of Current PENTA, WHO, and US Treatment Thresholds—Criteria for Initiating ART

Age	Staging system	PENTA 2009	US 2011	WHO 2010
0–11 months*		Treat all	Treat all	<24 months: Treat all
12–35 months	Clinical	CDC Stage B or C/WHO Stage 3 or 4	CDC Stage B or C	24–59 months: Clinical—WHO Stage 3 or 4 Immunological—CD4 % ≤ 25% or CD4 count ≤ 750 cells/mm <sup>3</sup>
	Immunological	CD4 % < 25% or CD4 count < 1000 cells/mm <sup>3</sup>	CD4 % < 25%	
35–59 months	Clinical	CDC Stage B or C/WHO Stage 3 or 4	CDC Stage B or C	≥5 yr: Clinical—WHO Stage 3 or 4 Immunological—CD4 count ≤ 350 cells/mm <sup>3</sup>
	Immunological	CD4 % < 20% or count < 500 cells/mm <sup>3</sup>	CD4 % < 25%	
≥5 yr	Clinical	CDC Stage B or C WHO Stage 3 or 4	CDC Stage B or C	
	Immunological	CD4 count < 350 cells/mm <sup>3</sup>	CD4 count < 500 cells/mm <sup>3</sup>	

Consider treating all children when HIV viral load greater than 100,000 copies/mL, regardless of clinical or immunological status.

\*Initiation of antiretroviral therapy is recommended for infants younger than 12 months, regardless of clinical status, CD4 percentage, or viral load.

**Table 86.4:** CDC 1994 Revised Classification System for HIV Infection in Children\*

<b>Category N: Not Symptomatic</b>
Children who have no signs or symptoms considered to be the result of HIV infection or who have only one of the conditions listed in category A
<b>Category A: Mildly Symptomatic</b>
Children with <b>two</b> or more of the following conditions but none of the conditions listed in categories B and C:
<ul style="list-style-type: none"> <li>• Lymphadenopathy (<math>\geq 0.5</math> cm at more than two sites; bilateral = one site)</li> <li>• Hepatomegaly</li> <li>• Splenomegaly</li> <li>• Dermatitis</li> <li>• Parotitis</li> <li>• Recurrent or persistent upper respiratory infection, sinusitis, or otitis media</li> </ul>
<b>Category B: Moderately Symptomatic</b>
Children who have symptomatic conditions, other than those listed for category A or category C, that are attributed to HIV infection. Examples of conditions in clinical category B include, but are not limited to, the following:
<ul style="list-style-type: none"> <li>• Anemia (<math>&lt;8</math> g/dL), neutropenia (<math>&lt;1000</math> cells/mm<sup>3</sup>), or thrombocytopenia (<math>&lt;100,000</math> cells/mm<sup>3</sup>) persisting for <math>\geq 30</math> days</li> <li>• Bacterial meningitis, pneumonia, or sepsis (single episode)</li> <li>• Candidiasis, oropharyngeal (i.e., thrush) persisting for older than 2 months in children aged older than 6 months</li> <li>• Cardiomyopathy</li> <li>• Cytomegalovirus infection with onset before age 1 month</li> <li>• Diarrhea, recurrent or chronic</li> <li>• Hepatitis</li> <li>• Herpes simplex virus (HSV) stomatitis, recurrent (i.e., more than two episodes within 1 year)</li> <li>• HSV bronchitis, pneumonitis, or esophagitis with onset before age 1 month</li> <li>• Herpes zoster (i.e., shingles) involving at least two distinct episodes or more than one dermatome</li> <li>• Leiomyosarcoma</li> <li>• Lymphoid interstitial pneumonia (LIP) or pulmonary lymphoid hyperplasia complex</li> <li>• Nephropathy</li> <li>• Nocardiosis</li> <li>• Fever lasting for greater than 1 month</li> <li>• Toxoplasmosis with onset before age 1 month</li> <li>• Varicella, disseminated (i.e., complicated chickenpox)</li> </ul>
<b>Category C: Severely Symptomatic</b>
<ul style="list-style-type: none"> <li>• Serious bacterial infections, multiple or recurrent (i.e., any combination of at least two culture-confirmed infections within a 2-year period), of the following types: septicemia, pneumonia, meningitis, bone or joint infection, or abscess of an internal organ or body cavity (excluding otitis media, superficial skin or mucosal abscesses, and indwelling catheter-related infections)</li> <li>• Candidiasis, esophageal or pulmonary (bronchi, trachea, lungs)</li> <li>• Coccidioidomycosis, disseminated (at site other than or in addition to lungs or cervical or hilar lymph nodes)</li> <li>• Cryptococcosis, extrapulmonary</li> <li>• Cryptosporidiosis or isosporiasis with diarrhea persisting for greater than 1 month</li> <li>• Cytomegalovirus disease with onset of symptoms at age greater than 1 month (at a site other than liver, spleen, or lymph nodes)</li> <li>• Encephalopathy (at least one of the following progressive findings present for at least 2 months in the absence of a concurrent illness other than HIV infection that could explain the findings): a) failure to attain or loss of developmental milestones or loss of intellectual ability, verified by standard developmental scale or neuropsychological tests; b) impaired brain growth or acquired microcephaly demonstrated by head circumference measurements or brain atrophy demonstrated by computerized tomography or magnetic resonance imaging (serial imaging is required for children younger than 2 years of age); c) acquired symmetric motor deficit manifested by two or more of the following: paresis, pathologic reflexes, ataxia, or gait disturbance</li> <li>• Herpes simplex virus infection causing a mucocutaneous ulcer that persists for greater than 1 month; or bronchitis, pneumonitis, or esophagitis for any duration affecting a child older than 1 month of age</li> <li>• Histoplasmosis, disseminated (at a site other than or in addition to lungs or cervical or hilar lymph nodes)</li> <li>• Kaposi sarcoma</li> <li>• Lymphoma, primary, in brain</li> <li>• Lymphoma, small, noncleaved cell (Burkitt), or immunoblastic or large cell lymphoma of B-cell or unknown immunologic phenotype</li> <li>• <i>Mycobacterium tuberculosis</i> infection, disseminated or extrapulmonary</li> <li>• <i>Mycobacterium</i>, other species or unidentified species, disseminated (at a site other than or in addition to lungs, skin, or cervical or hilar lymph nodes)</li> <li>• <i>Mycobacterium avium</i> complex or <i>Mycobacterium kansasii</i>, disseminated (at site other than or in addition to lungs, skin, or cervical or hilar lymph nodes)</li> <li>• <i>Pneumocystis jiroveci</i> pneumonia</li> <li>• Progressive multifocal leukoencephalopathy</li> <li>• Salmonella (nontyphoid) septicemia, recurrent</li> <li>• Toxoplasmosis of the brain with onset at older than 1 month of age</li> <li>• Wasting syndrome in the absence of a concurrent illness other than HIV infection that could explain the following findings: <ul style="list-style-type: none"> <li>a) persistent weight loss greater than 10% of baseline; OR</li> <li>b) downward crossing of at least two of the following percentile lines on the weight-for-age chart (e.g., 95th, 75th, 50th, 25th, 5th) in a child <math>\geq 1</math> year of age; OR</li> <li>c) less than fifth percentile on weight-for-height chart on two consecutive measurements, <math>\geq 30</math> days apart PLUS 1) chronic diarrhea (i.e., <math>\geq 2</math> loose stools per day for greater than 30 days), OR 2) documented fever (for <math>\geq 30</math> days, intermittent or constant)</li> </ul> </li> </ul>

percentage/count or plasma HIV RNA level as they have a higher mortality risk.<sup>26</sup>

### ASYMPTOMATIC OR MILDLY SYMPTOMATIC CHILDREN >1 YEAR

In children aged older than 12 months with clinical stage A or N disease, ART should be started when the CD4 count or percentage falls below age-specific thresholds. In addition, ART should be considered if the viral load exceeds 100,000 copies/mL.

See Table 86.3 for comparison of WHO, CDC, and PENTA guidelines on when to commence ART in children.

### What Initial Combination Therapy for Antiretroviral-Naïve Children

As for adults, first-line ART is usually with 3 drugs from 2 classes—2 nucleoside reverse transcriptase inhibitors (NRTIs) plus either a protease inhibitor (PI) or non-nucleoside reverse transcriptase inhibitor (NNRTI). See Boxes 86.2, 86.3 and 86.4 for summaries of the recommendations.

### WHICH NRTI BACKBONE?

In the US, a combination of abacavir, didanosine, or zidovudine plus either lamivudine or emtricitabine is the preferred NRTI backbone.<sup>27</sup> Lamivudine and abacavir can be given once daily to children older than 3 years, has superior long-term efficacy to lamivudine and zidovudine,<sup>28</sup> and can be given as a fixed dose combination (Kivexa) in older children.

#### Box 86.2 Types of Initial ART Regimens

**NNRTI-based**  
(1 NNRTI + 2 NRTI backbone)

**PI-based**  
(1 or 2 PIs + 2 NRTI backbone)

**3 NRTIs\***  
(ZDV + 3TC + ABC for use only in special circumstance)

\*The preferred first-line ARV regimen for infants and children younger than 2 years of age, who have been exposed to NVP and are taking a rifampicin-containing regimen for TB.

Abbreviations: NNRTI, non-nucleoside reverse transcriptase inhibitor; NRTI, nucleoside/nucleotide reverse transcriptase inhibitor; PI, protease inhibitor; ZDV, zidovudine; 3TC, lamivudine; ABC, abacavir.

#### Box 86.3 NNRTI-Based Regimens

**Preferred**  
NVP + 2 NRTIs: children aged younger than 3 years or requiring liquid formulation  
EFV + 2 NRTIs: children aged ≥3 years

**Alternative**  
NVP + 2 NRTIs (aged ≥3 years)

**Box 86.4** PI-Based Regimens**Preferred**

LPV/RTV + 2 NRTIs (all ages)

**Alternative**ATV + low-dose RTV + 2 NRTIs (children aged  $\geq 6$  years)FPV + low-dose RTV + 2 NRTIs (children aged  $\geq 6$  years)**Use in special circumstances**

ATV (unboosted) + 2 NRTIs (treatment-naïve adolescents age  $\geq 13$  years and  $>39$  kg who are unable to take RTV [must be boosted with RTV if used with TDF]), FPV (unboosted) + 2 NRTIs (children aged  $\geq 2$  years)

Abbreviations: LPV, lopinavir; RTV, ritonavir; ATV, atazanavir; FOS-APV, fosamprenavir; TDF, tenofovir disoproxil fumarate.

The choice of whether to add a PI or NNRTI to the dual NRTI backbone was addressed in the PENPACT1 Study. No immunological, virological or clinical difference was seen between the treatment groups, with 71% remaining suppressed on first-line therapy at 4 years of follow-up.<sup>29</sup>

With NNRTIs, single-point mutations in the reverse transcriptase gene can cause resistance which may develop after only a few missed doses. Cross-resistance occurs between efavirenz (EFV) and NVP, rendering both drugs futile for future regimens. Etravirine (ETR) a new twice daily NNRTI, licensed in treatment experienced adults is entering phase II trials in children.<sup>30</sup> The correct EFV dose has not been determined in children younger than 3 years and NVP should be used in this age-group. EFV syrup is available, but because of reduced bioavailability, care must be taken as the liquid dose is larger than the capsule dose. Efavirenz can cause neuropsychological side effects and mood swings and is best given at night-time. It is contraindicated in pregnancy and care needs to be taken when prescribing to post-pubertal girls.

PI-based regimens spare NNRTIs and efficacy and potency are well documented. Unlike NNRTIs, resistance requires multiple mutations thus PI-based regimens are less fragile and may be preferable in situations such as adolescence where adherence may be poor.

PI use in children should be ritonavir boosted to optimize drug levels. In children, there is most data on ritonavir boosted lopinavir (LPV/r) (Kaletra) which is also the only PI with both lopinavir and ritonavir combined in either a tablet or liquid formulation.<sup>31</sup> The syrup lacks palatability (contains alcohol 45%). ATV/r (ritonavir boosted atazanavir), fosamprenavir (FOS-APV)/r, tipranavir (TPV)/r, and darunavir (DRV)/r have comparable efficacy with LPV/r in adults. ATV/r and FOS-APV/r are licensed for older children while DRV/r and TPV/r are now licensed for treatment experienced children over 6 and 2 years of age, respectively.

Lopinavir/r (LPV/r) remains the drug of choice for infants and young children ( $<6$  years).

For teenagers ATV/r or DRV/r may be preferable due to once daily dosing. Metabolic complications and multiple drug interactions are potential limiting factors with PI-based regimens. PIs generally have a higher pill burden than NNRTIs.

**TRIPLE-NRTI REGIMEN (ZIDOVUDINE/LAMIVUDINE/ABACAVIR)**

Triple-NRTI regimens should only be considered in special circumstances as they are less potent than NNRTI- or PI-based regimens with higher rates of virological failure. However, they may be considered in children aged less than 3 years with TB co-infection due to interactions of NVP and PIs with rifampicin.

**Prophylaxis Against Opportunistic Infections (OIs)**

Prophylaxis against *Pneumocystis* with cotrimoxazole should be given to all HIV-infected infants from age 1 month until their first birthday.<sup>32</sup> Children aged 1–4 years should receive prophylaxis if their CD4 count is below 500 cells/ $\mu$ L or 20% of total lymphocyte count while children aged 5 years and upwards should receive prophylaxis if they have a CD4 count below 200–250 cells/ $\mu$ L or less than 15%.

**Monitoring of Children on Antiretroviral Therapy**

The aim of ART is to achieve an undetectable viral load ( $<50$  copies/mL plasma) and CD4 reconstitution. Monitoring needs to be more frequent shortly after initiating or changing therapy, but once children are established on treatment and stable, clinic visits can be 3 to 4 monthly.

Therapeutic drug monitoring (TDM) is not widely available for NRTIs as intracellular levels of the active metabolite are complex to measure. TDM of NNRTIs and PIs are useful if there is suspected drug toxicity, poor adherence, drug interactions, or failure to suppress viremia despite apparent good adherence.

**ADHERENCE**

Adherence is of paramount importance for long-term efficacy of ART and infants and younger children rely on caregivers to deliver this. Adherence is particularly poor in adolescence. PI regimens are more suitable in those where adherence is not ideal as PI resistance requires multiple mutations unlike NNRTIs where a single mutation can result in cross class resistance. Once daily medication regimens, choice of formulation and pill boxes/calendars/diaries/peer support can help with adherence.

Drug adherence may be affected more by common side effects, for example, diarrhea due to lopinavir/r, dysphoria caused by efavirenz, nausea due to zidovudine.

**DRUG TOXICITIES**

The common drug toxicities experienced with ART are summarized in Box. 86.5. Longer term side effects of antiretroviral are becoming increasingly apparent as the cohort of children with perinatally acquired HIV infection ages, with many entering adolescence and young adult life exposed to ART for over a decade.<sup>33</sup> Some adverse effects, such as lipid derangements and

**Box 86.5** Common Drug Toxicities

- Hematological adverse events associated with drug-induced bone marrow suppression, e.g., zidovudine
- Mitochondrial dysfunction, primarily seen with NRTI drugs—lactic acidosis, hepatic toxicity, pancreatitis, and peripheral neuropathy
- Lipodystrophy and metabolic abnormalities, primarily seen with stavudine and PIs, and to a lesser degree with NRTIs (fat maldistribution and body habitus changes; hyperlipidemia; hyperglycemia, insulin resistance, diabetes mellitus; osteopenia, osteoporosis)
- Allergic reactions such as skin rashes and hypersensitivity reactions, common with NNRTI drugs, also seen with NRTI drugs, e.g., abacavir

hepatitis, may be due to either ART or HIV itself. Abacavir (ABC) hypersensitivity is associated with the HLA-B5701 allele, and may be fatal if the drug is re-introduced after a reaction. Children with HLA-B5701 should not be given ABC and screening should be adopted as routine practice where possible, particularly in non-Africans.<sup>34</sup>

PIs and the NRTI stavudine have been implicated in the development of fat redistribution syndrome (FRS) and the risk of lipodystrophy and probability of intra-abdominal fat accumulation increase with the duration of PI therapy. NRTIs are associated with lipoatrophy and again development increases with duration of therapy.

Regarding bone health, HIV infection in children has been associated with poor growth, delayed puberty, reduced bone mineral density, and vitamin D deficiency—all factors that may impact on long-term bone health. Concerns about the potential effects of tenofovir on bone mineralization and renal function in children and adolescents exist.<sup>35,36</sup>

Adults with HIV infection are at increased risk of cardiovascular disease (abacavir and to a lesser extent didanosine have been associated with an increased risk of myocardial infarction) and while data is less clear in pediatric populations, comparable risk factors of dyslipidemia, altered glucose metabolism, inflammation and immune activation are increasingly described.

**TREATMENT INTERRUPTIONS**

Potential benefits of planned treatment interruptions (PTI) in children with good CD4 counts include reduced cumulative drug toxicity, possibly reduced viral resistance associated with poor adherence, and improved quality of life.

Largely because of the SMART trial results, treatment interruptions are no longer recommended in adults on suppressive HAART.<sup>37</sup> However, results from the PENTA 11 trial of 109 HIV-infected children, randomized to PTI versus continuous therapy over 72 weeks showed no serious clinical outcomes. On reintroduction of ART younger children had better CD4 % recovery after PTIs and long-term follow-up is ongoing.<sup>38</sup>

**TREATMENT FAILURES**

Treatment failure is defined as suboptimal response or a lack of sustained response to therapy using virologic, immunologic, and clinical criteria.

**Virological failure** is defined as a persistent viral load above 5000 RNA copies/mL, after at least 24 weeks on ART.

**Immunologic failure** is defined as developing or returning to the following age-related immunological thresholds after at least 24 weeks on ART.

- CD4 count of less than 200 cells/mm<sup>3</sup> or % CD4+ less than 10 for a child 2 years or older to younger than 5 years of age
- CD4 count of less than 100 cells/mm<sup>3</sup> for a child 5 years of age or older.

**Clinical failure** is defined as the appearance or reappearance of WHO clinical stage 3 or stage 4 events after at least 24 weeks on ART.

It is important to recognize that not all instances of treatment failure require an immediate change in antiretroviral therapy. Causes need to be addressed, and should include poor adherence to therapy, medication intolerance, inadequate dosing, poor absorption of medications, drug–drug interactions and drug resistance.

In considering second-line therapy, if a child has received initial therapy with an NNRTI-based regimen, change to a PI-based regimen is recommended and vice versa.

New ART regimens following treatment failure should be chosen based on treatment history and drug-resistance testing.

Management of drug resistance can be challenging in treatment-experienced children. Referral to a pediatric HIV specialist is preferred at this stage. Darunavir/rtv, Tipranavir/rtv, and Enfuvirtide(T-20), a fusion inhibitor may be considered where multidrug resistance has occurred and are licensed for children in this setting. T-20 must be administered subcutaneously twice daily and is associated with a high incidence of local injection site reactions (98%).

Where patients are failing on ART regimens approved for their age, use of investigational agents or agents approved for older age groups can be considered. While pediatric data is limited, the combination of etravirine, darunavir/r and the integrase inhibitor raltegravir given to 12 heavily pretreated French adolescents at standard adult doses resulted in 11 patients achieving a viral load of less than 400 copies/mL after a year.<sup>39</sup> Phase II safety and pharmacokinetic studies of raltegravir in treatment experienced children age 2–18 years are ongoing and initial data is encouraging.<sup>40</sup> Etravirine is an NNRTI that may retain antiviral activity even in the presence of NNRTI resistance-associated mutations induced by NVP or EFV. Maraviroc, a CCR5 receptor antagonist acts by blocking R5-trophic HIV entry into CD4 cells and pharmacokinetic, safety and efficacy studies of maraviroc and an optimized backbone in treatment experienced CCR5 tropic 2–17 year olds are ongoing and include a liquid formulation.

Resistance testing should take place while the child is on therapy with a detectable plasma viral load, because predominant

plasma viral strains may quickly revert to wild-type once drug pressure is removed. Thus, if a child with prior therapy develops resistant virus and then stops therapy, wild type virus may dominate in the absence of therapy. In this situation, resuming the prior therapy would fail to suppress the virus because the resistant virus would again emerge.

## Co-Infections in the Setting of HIV—HBV, HCV, TB

### HEPATITIS B (HBV)

There is well-documented interaction between HIV and HBV infection, with increased rates of hepatotoxicity. Some ARVs have activity against HBV (3TC, FTC, tenofovir). ART regimens in co-infected patients should, where possible, contain either two drugs active against HBV (usually TDF with either 3TC or FTC) or none. For adolescents more than 12 years of age with hepatitis B, the preferred regimen is tenofovir (TDF) + emtricitabine (FTC) or 3TC + NNRTI.<sup>41</sup> If HBV requires treatment in a patient whose HIV does not yet require treatment, then use of drugs also active against HIV (e.g., entecavir) without additional ART should be avoided to prevent development of HIV resistance.

### HEPATITIS C (HCV)

HCV co-infection also increases the risk of liver toxicity, but long-term follow-up data for co-infected children is sparse. No anti-HIV ART drugs are effective against HCV; however there is an increased risk of hepatotoxicity with ART which needs to be monitored. In addition, ART can interact significantly with drugs used to treat hepatitis C, e.g., ribavirin.

### TB

There are particular difficulties of TB diagnosis, drug interactions, and immune reconstitution disease in HIV-infected children. The standard treatment with four antituberculous drugs is recommended, but rifampicin significantly interacts with NVP and PIs, generally reducing their drug levels. Rifabutin may be used instead of rifampicin to reduce interactions or EFV-based regimens or triple nucleoside regimens may be used. The relative timing of ART and antituberculous treatment depends on the degree of pre-ART immune suppression. With a CD4 count above 200 cells/mm<sup>3</sup>, it may be possible to treat the TB first and start ART later. However, if the child has significant immune suppression and is at risk of disease progression, ART should not be delayed and a combination of rifabutin with NVP or efavirenz and two NRTIs is advised. Useful information on drug interactions can be found at [www.hiv-druginteractions.org](http://www.hiv-druginteractions.org). The syndrome of immune reconstitution (IRIS) occurs in children with TB, usually developing around 3 to 4 weeks after starting treatment with worsening of respiratory symptoms, particularly in children who have a low pre-ART CD4 count and high viral load and starting ART within 2 months of starting with

TB treatment. ART should be continued, but steroids may be necessary to manage IRIS.

## Management of Pediatric HIV in Resource-Limited Settings

Management in resource-limited settings faces several challenges.

### IDENTIFICATION OF HIV INFECTED CHILDREN NEEDING TREATMENT

The ideal entry point should be at an antenatal clinic with the offer of HIV screening to all pregnant women, and the use of interventions to prevent MTCT of HIV, for example, antiretroviral drugs, caesarean section, and consideration of provision of infant formula in those women found to be infected with HIV. Infants born to HIV-positive mothers should be followed for clinical symptoms and signs of HIV infection and be tested for HIV. In this scenario, infants are identified early and receive ART in a timely fashion. However, in resource-limited settings with a high prevalence of HIV infection, and a large proportion of the pregnant women not knowing their HIV status, physicians should consider screening strategies among infants accessing medical services. In a recent South African study, HIV testing was performed universally in all 6-week-old infants attending the immunization clinic; 9.2% were diagnosed with HIV.<sup>42</sup> In a Zambian setting, routine HIV testing for all hospitalized pediatric patients (median age of 12 months [interquartile range: 0–24 months]) at a university teaching hospital, identified 29.2% as HIV infected.<sup>43</sup>

### ACCESS TO TREATMENT AND CARE

Timely access to treatment poses a great challenge in resource-poor settings for HIV-infected children. Even though current guidelines recommend initiation of ART when CD4 count is less than 350 cells/mm<sup>3</sup> in older children, and CD4 % is less than 25% in younger children, data from meta-analysis of 15 pediatric cohorts in Asia and Africa showed that median CD4 at initiation of ART is only 8.1%.<sup>44</sup>

### ANTIRETROVIRAL DRUGS FORMULA

Large scale implementation of pediatric antiretroviral treatment programs in resource-limited settings has been feasible due to several factors:

- Generic antiretroviral therapy has significantly increased access to treatment
- Efforts to provide pediatric antiretroviral tablets is crucial, despite antiretroviral syrup formulation being more accurate in term of dosing for infants and young children. Owing to high cost, short shelf-life, and difficulties in logistics, syrup formulations are not feasible under many field conditions.
- Currently, there are several solid formulation and pediatric fixed-dose combination (FDC) available for children of vary-

ing size (e.g., Baby FDCs of d4T 6 mg/3TC 30 mg/NVP 50 mg; Junior FDCs of d4T 12 mg/3TC 60 mg/NVP 100 mg). Some are scored or chewable tablets.

- The weight-banded simplified ARV table provided by the WHO working group is very helpful for large scale programmes compared to individual dose calculations using dose per kilogram or body surface area.<sup>45</sup>

## HIGH RISK OF DEVELOPMENT OF IRIS

The risk of IRIS developing is particularly high in children who have a low pre-ART CD4 count and high viral load. The incidence of IRIS among HIV-infected children in resource-limited settings is reported in the range of 19–38%.<sup>46</sup> The common organisms associated with IRIS in children are mycobacteria (tuberculosis, BCG-associated IRIS and non-tuberculosis mycobacterium) and herpes virus infection, for example, cytomegalovirus. IRIS should be considered when patients present with symptoms shortly after commencing ART. Unmasking of IRIS generally requires treatment of the opportunistic infection. Most cases of paradoxical IRIS (i.e., symptoms of IRIS despite appropriate OI therapy) resolve spontaneously, or can be managed with non-steroidal anti-inflammatory drugs. Occasionally IRIS becomes progressively worse and may require a short course of treatment with corticosteroids and rarely, a temporary discontinuation of ART.

## Guideline for First-Line and Second-Line Antiretroviral Therapy for Children in Resource-Limited Settings

WHO 2010 guidelines recommend initiating ART to all children diagnosed before 2 years of age where CD4 testing is not available due to high morbidity and mortality, children 2–5 years with CD4% less than 25% or 750 cell/mm<sup>3</sup> and children older than 5 years with CD4 count less than 350 cell/mm<sup>3</sup>. The recommended first-line regimen is non-nucleoside reverse transcriptase (NNRTI) plus 2 nucleoside reverse transcriptase inhibitors (NRTIs). Monitoring after initiation of ART relies mostly on clinical and immunological indices as access to HIV viral load testing to confirm treatment failure is limited. This leads to late detection of treatment failure and more risk of development of HIV viral mutations associated with multidrug resistance. A report from HIV-infected children with treatment failure detected by HIV RNA monitoring every 6 months showed only 8% with multi-NRTI drug resistance.<sup>47</sup> However when the treatment failure was detected by clinical or immunological criteria, multi NRTI drug resistance was reported to be up to 36%.<sup>48</sup>

The criteria for switching to second-line regimens recommended in the WHO 2010 guidelines are more conservative, using a public health approach, than US or PENTA guidelines, but are based on limited evidence. The immunologic criteria for switching are CD4 count less than 200 cell/mm<sup>3</sup>, or CD4 % less than 10% for

children younger than 5 years, and CD4 count less than 100 cell/mm<sup>3</sup> for children older than 5 years. Virologic failure is defined as HIV RNA greater than 5000 copies/mL. The recommended second-line regimen is re-cycling 2 NRTI plus protease inhibitors. More data are needed on the efficacy of second-line regimens, using WHO criteria, when a high rate of multi-drug resistance NRTI is expected, which may make an NRTI backbone less effective.

## Conclusion

Understanding the principles of selecting ART regimens and vigilance of potential toxicities are essential for optimal management of HIV-infected infants and children. The greatest challenge lies in maintaining adherence to medications so physicians need to advise a regimen which is tolerable, simple yet effective, and potent yet without a huge pill burden.

### Summary

- With successful interventions the risk of mother-to-child HIV transmission can be reduced to less than 1%.
- Breast-feeding should be avoided to prevent postnatal MTCT. However, if not possible, as in some settings, strategies to minimize breast milk transmission include exclusive breast feeding and/or antiretroviral prophylactic regimens (maternal or infant or both).
- ART has markedly reduced mortality and morbidity including improved growth and neurocognitive function among children and adolescents infected with HIV-1.
- CD4+ve lymphocyte %ages rather than absolute count is a more reliable marker of immune status in young children until about six years of age when counts resemble those of adults.
- All infants younger than 12 months of age should start ART regardless of their CD4 % or count, HIV viral load and clinical state.
- In areas where CD4+ve lymphocyte testing is not reliably available, WHO 2010 recommend that children between the ages of 12–24 months also start ART.
- In older children, ART should be initiated based on immunological and clinical parameters (Table 86.3).
- An NRTI-backbone with either a boosted PI or an NNRTI is the preferred regimen in ART-naïve patients.
- PI regimens are more suitable in those where adherence is not ideal as PI resistance requires multiple mutations.
- Dosing in children varies considerably from adults owing to differing pharmacokinetics but ART is generally well tolerated.
- Referral to a pediatric HIV specialist is advised when resistance develops in treatment-experienced children.
- With co-existing TB, the relative timing of ART and antituberculous treatment depends on the degree of pre-ART immune suppression.
- Risk of IRIS developing is high in children with a low pre-ART CD4 count and high viral load.
- Challenges remain in resource-poor countries: identification of HIV in pregnant women, identification of HIV-infected children in need of treatment, access to ART, dual infections particularly TB and high risk of development of IRIS.

## HIV Infection in Homosexual Men

Mark Bloch • Brian P. Mulhall  
• Charles Farthing • Richard Hillman

### Introduction

On June 5, 1981, the Centers for Disease Control (CDC) (Atlanta, USA) published a report of five cases of *Pneumocystis carinii* pneumonia (PCP) among previously healthy young men in Los Angeles.<sup>1</sup> This report is sometimes referred to as the “beginning” of HIV/AIDS, but it might be more accurate to describe it as the beginning of the general awareness about AIDS in the USA. A few months later, a 49-year-old man was admitted to the Brompton Hospital in London suffering from PCP, thought to be the first case of AIDS in the United Kingdom.<sup>2</sup> The first case of AIDS in Australia was diagnosed in November 1982.<sup>3</sup> Within 18 months, epidemiologists from CDC conducted studies and prepared *MMWR* reports that identified all of the major risk factors for AIDS, and a compendium is available.<sup>4</sup> There then followed dramatic social, public health and clinical responses, graphically described by Randy Shilts.<sup>5</sup>

The epidemiology of HIV is covered elsewhere in this volume in comprehensive detail. For the purposes of this chapter, we have introduced the chronology of HIV in men who have sex with men (MSM)/homosexual men, because all of the present authors began their careers as HIV clinicians at about this time, between the years 1984 and 1987, and have since practiced for many years in one or more of these countries; United Kingdom, United States of America, and Australia. The majority of our patients have been homosexual men, or MSM, although we have treated others, and in other countries.

### Background

Despite figures suggesting that <10% of the male population engaged in same sex activity,<sup>6</sup> MSM are over-represented in the epidemiology of HIV throughout the world.<sup>7</sup> In many developed countries, MSM account for the largest proportion of new diagnoses and in regions such as Asia, for example, the reported proportion of MSM infected with HIV ranges from 10% to 42%.<sup>7</sup>

In the United Nations General Assembly High-Level Meeting on AIDS, in June 2008, fewer countries reported on services for

MSM than for any other. Furthermore, those reports that were made available reflected, lower coverage levels for MSM than for the general population or for other most-at-risk populations (UNAIDS).

Homosexual activities are illegal in most countries and remain heavily stigmatised, even in areas where legal protections exist.<sup>8</sup> Thus, it is difficult to derive truly meaningful figures for the proportions of MSM who are infected with HIV. Convenience samples from locations such as STI clinics typically yield rates of 1–20%<sup>9</sup> and community rates are likely to be lower.

Thus, the majority of MSM are not infected with HIV, yet are often stigmatised as such by the general (and sometimes medical) communities. Even when not infected, awareness of HIV is typically much higher among MSM than in the general community—with correspondingly greater condom usage than in the heterosexual community.<sup>10</sup>

In MSM, HIV infection is most commonly acquired through unprotected anal intercourse (UAI), especially when multiple partners are involved.<sup>11</sup> Thus, it is generally found in the minority of MSM who have UAI in their sexual repertoire, together with frequent partner change. Taking a detailed sexual history is therefore essential in assessing potential risk for HIV infection and for comprehensive care of those already infected.

MSM may not see themselves as “gay”, and heterosexually-identifying men sometimes engage in same sex activities in environments such as prisons.<sup>12</sup> The rapid spread of HIV, hepatitis and other STIs may therefore occur in these conditions as a result of a combination of factors, including: non consensual sexual activity, lack of condoms, illicit drug use, poor access to clean injecting equipment, high background rates of infections in deprived populations, and often inadequate management of those with existing HIV infection.

### Provision of Health Services

Social and political barriers greatly impede the recognition of the extent of the problem of HIV infection in MSM. This, in turn, makes the delivery of effective healthcare difficult and creates

barriers to prevention efforts aimed at reducing the spread of HIV within the MSM community and inevitably, to the wider community. In order to facilitate presentation to MSM-friendly services, there needs to be outreach via good community links, advertising, use of the internet communication and word of mouth. Whether the clinic forms part of a general medical facility or part of a general sexual health service or even a specific MSM-targeted practice, the physical context of the facilities is important. Ideally the clinic should be located with ready access to transport, in an area convenient to the population it serves. The entrance needs to be situated to provide discretion and privacy, yet sufficiently recognizable to the target population, for example by using the internationally recognized “rainbow flag”.

The most important features for the provision of services include:

- i) a confidential and safe environment
- ii) staff that understand the needs of their patients (staff drawn from the MSM community, or others who are sensitive to MSM issues)
- iii) training and expertise in the needs of HIV-infected MSM
- iv) adequate time to address issues

The waiting room and facilities would be ideally decorated in a way to make patients feel comfortable and at ease. This can be achieved by avoidance of harsh lighting, the colors, and friendly communications with the staff.

The waiting room offers an opportunity to provide educational materials such as posters, pamphlets and booklets which can be placed to allow waiting patients reading material and information. It also provides an opportunity to reassure the patients that the staff understands issues such as confidentiality and local aspects of MSM lifestyles. Beyond the clinic, it is important to consider how the internet may be used to enhance services. This may be in a variety of ways, such as sources of reliable information, social networking sites, risk assessments, booking of appointments and results made available.

A detailed knowledge of current and potential risk activities is essential to the appropriate provision of preventative messages, safer sex devices and clean injecting equipment. One of the key skills for the treating physician is therefore, the ability to create an environment of trust, where the patient is clear about confidentiality. However, the potential implications of disclosure of illegal activities need to be explicitly negotiated with the patient. This may impact on areas such as:

- i) disclosure of illegal activity such as “homosexual behavior”, injecting drug use, sex work and under age sexual activity
- ii) notification of HIV positive diagnoses to authorities in identifiable, coded or de-identified formats
- iii) dealing with situations where there may be risks of onwards transmission, including unsafe sexual and injecting behaviors
- iv) lack of disclosure of the HIV status by the patient in sexual, work and social settings

It is thus important to become familiar with the rules of the local jurisdiction.

## Recreational Drug Use

Rates of recreational drug use such as cigarette smoking, alcohol, and illicit drugs are higher in MSM compared to the general population.<sup>13–15</sup> This has a number of potential impacts on HIV infected MSMs:

- i) These lifestyle factors are often associated with other risky behaviours, such as frequent partner change and failure to use condoms.<sup>16</sup>
- ii) Increased risks of cardiovascular disease and malignancies related to smoking are compounded by HIV infection.
- iii) Illicit drug use, particularly drugs such as crack, cocaine, crystal, and methamphetamine, may increase rates of unsafe sexual activity.<sup>17</sup>
- iv) Unsafe injecting may increase the risk of HIV transmission and the acquisition of viral hepatitis. Individuals co-infected with hepatitis may have more rapidly progressing disease. Superinfection with another strain of HIV may cause additional problems, particularly in the context of the acquisition of resistant virus.
- v) The generally chaotic lifestyle usually associated with stimulant drugs such as cocaine and amphetamine, usually leads to major problems with adherence to antiretroviral therapy (ART) and other therapies.
- vi) Certain recreational drugs may impact on the metabolism of prescribed medications, with potentially adverse consequences.
- vii) Sildenafil and similar drugs may be used, either for *bona fide* erectile dysfunction, or to enhance existing sexual performance. Drug interactions may occur with prescribed medications, together with the potential for increased onward transmission of HIV and other STIs.

An accurate history of recreational drug use, including smoking, alcohol and illicit drug consumption is therefore essential to effective management. It facilitates the provision of targeted, appropriate advice to reduce potential harm to the individual and others. However, insistence on abstinence is not only unlikely to result in behavior change, it may have a negative impact on any trust in the therapeutic relationship and reduce the likelihood of any further disclosure of risk activities. The key focus should therefore be on harm minimisation, rather than stopping all activities that are potentially harmful. However, in certain circumstances total abstinence may be the only viable option.

In general, unless the need for antiretroviral drug (ARV) therapy is particularly urgent, dependency issues should be addressed prior to initiation of ART. Patient motivation is crucial for this process to occur. Depending on the extent of the problem, simple advice, specialist counsellors and specific medications may be required. In extreme cases, directly observed therapy has been effectively used to ensure good adherence to

ARVs in patients taking illicit drugs. This is difficult to do, but for patients on methadone programs it is somewhat easier to organize.

## Sexual Practices

A good understanding of sexual practices of MSM is important to be able to effectively provide advice, testing, and management.

Men negotiate sexual partners in a number of different contexts, and, increasingly, via the internet. They engage in a wide variety of sexual practices, many of which are low risk from the perspective of the transmission of HIV and other STIs. In addition to frottage, oro-genital, oro-anal and penile-anal intercourse, MSM may also practise techniques such as sado-masochism, water sports, fisting, the intra-anal insertion of drugs, and scatting. Knowledge of what these practices are, and the potential health and transmission consequences of them, is therefore required to provide informed advice.

“Barebacking” is the term used for unprotected anal sex and is practised by some men who feel that the use of condoms significantly reduces the pleasure of sex. It has significant potential for the transmission of HIV and other STIs. Sometimes it is practised by those wishing to become infected by HIV (to fit in with friends or to remove subsequent concern about being infected), and men doing this are sometimes referred to as “Bug chasers”.

In the 1990s, when it was realized that many new infections were contracted within the context of new relationships, a strategy of “negotiated safety” was developed. This approach involves partners initially testing for HIV and STIs, engaging in only protected sexual activity for a window period (typically of three months), re-testing and, if both negative, considering dispensing with protected activity within the context of the relationship. The level and form of contact activity outside the primary relationship is then negotiated between the partners. This strategy has been successful at reducing HIV infection within the context of new relationships. However, it does require a high level of open and honest communication between partners and may be more suitable for MSM who are gay-identified. In general, though if a sexual indiscretion occurs in a “committed relationship”, the last person to be informed will be the partner. Advice to always use safe sex within a committed relationship should probably therefore always be proffered.

“Sero-sorting” involves seeking partners of the same HIV status. Part of the impetus for this arose as a result of discrimination against HIV positive MSM by HIV negative MSM and their desire to avoid potential rejection when disclosing their status. In this manner, HIV positive men will only have unprotected sex with other men who know they are also infected, but it can still potentially lead to the transmission of other STIs and HIV superinfection. Likewise seroconcordant HIV negative partners can still transmit other STIs and potentially acquire HIV if a participant is unaware of their HIV status or seroconverting. Seronegative consensual unsafe sex actually is dangerous for HIV transmission as well. If a man becomes acutely infected

with HIV it is at that time that his viral load is the highest and that transmission is most likely to occur (several papers having postulated that the majority of transmission in fact occurs from acute seroconverters). A man unknowingly undergoing seroconversion may fairly recently have had a negative HIV test and will tell prospective partners that he is “HIV negative”.

“Strategic positioning” may be chosen in the context of known HIV sero-discordant partners. The HIV positive partner adopts the receptive position during anal sexual activity, reducing the risk of HIV transmission. This may reduce risk somewhat but of course most heterosexual men contract the disease from active sex so it is at best only partly protective for the active partner. Many physicians, and several guidelines, now recommend treating the positive partner of a serodiscordant MSM couple, as treatment for prevention—regardless of what the man’s immune status (CD4 count) may be.

Sero-sorting thus relies on partners knowing their HIV status and being honest in the disclosure of their status, where this is known. The window period involved in HIV testing and the greater transmissibility of HIV during the time of primary HIV infection reduce the reliability of sero-sorting as a strategy. Despite these potential drawbacks, sero-sorting has had some success in reducing HIV transmission, but is less effective than use of condoms, and does not prevent the transmission of other STIs.

Although large randomized trials in Africa have conclusively demonstrated a potentially useful role for male circumcision in the prevention of HIV and other STI transmission in the heterosexual community,<sup>18–22</sup> the evidence for value in MSM is less clear.<sup>23</sup> This is not surprising since it would theoretically only benefit those men whose sexual repertoire only included an insertive role.<sup>23–26</sup>

## Emotional Needs

Once a person becomes HIV-positive, previously fit young men may experience profound loss of control over their life and this may compound issues of low self esteem. Approval may be lost from loved ones, including family. They also have to suddenly deal with the medicalization of life, with a whole new world of knowledge, rules, tests and medications.

HIV positive MSM may be quite socially isolated and lack good social support. They may also be reluctant to disclose their status to others in the MSM community, because of justifiable fears of ostracism. Furthermore, disclosing one’s HIV status may impact on the ability to find partners and there may be legal obligations to do this prior to engaging in any form of sexual activity. The development of facial lipodystrophy may effectively disclose HIV status and some men may avoid starting ART because of fear of it. With the avoidance of the use of thymidine-analog NRTIs in ART, the patient can be reassured that the occurrence of lipodystrophy is very unlikely. If lipodystrophy has occurred, men may understandably, seek out cosmetic procedures to improve their appearance. Concealment of medications may

also be necessary to avoid their discovery, and this may compound difficulties with adherence.

Finding a doctor who listens, works with the patient and has the requisite medical expertise, may be difficult, but is critical to effectively face the many challenges of HIV infection. Appropriate support, counselling, and social services may have profound benefits.<sup>27</sup>

## Developing Countries

Because of stigma against MSM activity, the contribution of MSM-acquired HIV infection is often under-reported in developing countries and may not be accurately reflected in national surveillance data. Only ten countries worldwide (in North America, Europe, Australasia, and Africa) currently have legislation recognizing same sex relationships on an equal footing as heterosexual ones. Even in these parts of the world, discrimination may still cause significant problems in delivering effective healthcare and prevention strategies. According to The International Lesbian and Gay Association,<sup>28</sup> 78 countries actively criminalize consensual same sex acts among adults (2009 data), and most other countries adopt some form of discriminatory legislation. This is despite the fact that in some areas, such as Latin America, MSM contact is the predominant method of HIV transmission. In countries of Eastern Europe, Asia and Africa, rates of HIV in MSM are significantly higher than in the general population.

MSM, more frequently than in the developed countries, may not identify as “gay,” depending on local social mores, and different degrees of openness. As a consequence, MSM sexual activity is frequently clandestine, with even marriage to a woman and parenting. Such behaviors may therefore facilitate spread of HIV to the heterosexual community.

MSM may be at particular risk of HIV in developing countries for a number of reasons, including:

- i) poor knowledge regarding safer sex practices,
- ii) psychological denial of their risky practices,
- iii) lack of access to condoms and lubricants,
- iv) high background rates of other STIs,
- v) reluctance to seek healthcare for fear of discrimination,
- vi) low testing rates, with consequent lack of knowledge of HIV status, and
- vii) commercial sex work.

Healthcare workers in developing countries therefore have many challenges delivering effective HIV care to MSM as a result of stigma, legal difficulties and reluctant colleagues. More research is clearly required to identify optimum methods of delivery.

## Asia

Unprotected sex in MSM with multiple partners is one of the three main modes of transmission of HIV in the Asia-Pacific region, the other two being unprotected sex in the context of sex work, and unsafe injecting drug use.<sup>29</sup> There are several million MSM in the Asian region.<sup>30</sup>

MSM are up to 25 times more likely to be living with HIV compared to the general population.<sup>31</sup> MSM in urban areas of Thailand, Cambodia, and Myanmar are experiencing severe HIV epidemics with prevalence >10%. MSM in cities in Vietnam, Laos, Indonesia, China, Nepal, and India face intermediate level epidemics with prevalence of 2–10%.<sup>30</sup> Emerging epidemics in MSM are now evident in Pakistan, Bangladesh, East Timor, and the Philippines. There are also alarming rates for other STIs, particularly syphilis (for example 11% among MSM in China: Chen XS, personal communication). A series of amFAR documents in 2007–2009<sup>32,33</sup> pose the question, when so many resources are devoted to HIV, how could the entire international community have overlooked or simply ignored the rapidly rising rates of HIV infection among MSM? Part of the answer it seems lies in the stigma and violence surrounding MSM; in Asia and the Pacific, eleven countries have laws that criminalize consensual sexual activity among persons of the same sex. Institutionalization of a “culture of hatred” results in covert and overt discrimination and a denial that sex between men actually occurs. “The generalized discomfort with male-to-male sex has helped generate a familiar vicious cycle; no data equals no problem; no problem equals no intervention; and no intervention equals no need to collect data”.<sup>34</sup> For much of the last decade less than half the countries in the region did not include MSM in any form of sentinel data collection, nor include MSM in their national AIDS plans.

It is clear that there are diverse MSM identities in Asia; a glossary that would include transgender, overtly feminine acting MSM, overtly masculine acting MSM, gay men, men who have situational sex with other men. In other words there is a continuum; and it may be very difficult for outsiders, perhaps especially, western epidemiologists, to grasp the nuanced nature of MSM in Asian countries. In terms of sexual behaviours, a kaleidoscope of multiple unions is possible. Multiple sex partners are a common theme, however, and condoms may have to take second place to fleeting encounters, or indeed, emotional desire.<sup>35</sup>

A number of key researchers have been sounding the alarm on MSM and HIV in Asia for some time.<sup>31,36,37</sup> Many non-governmental organizations (NGOs) have also been active, for example Family Health International, which has supported several initiatives,<sup>38</sup> which resulted in an important and innovative resource—Practical Clinical Guidelines for Sexual Health Care of Men who have Sex with Men; these are available on the IUSTI Asia Pacific website.<sup>39</sup> The challenges for MSM programs are various and include the fact that many MSM do not identify as such and so are hidden from MSM-specific programming, as well as continuing prejudices.

Recently, there have been some crucial surveys and documents that support major funding for MSM in Asia, with specific attention to these issues.<sup>30,32,33</sup>

## Pacific

In the Pacific region, on the other hand, gender inequality and gender-based violence are considered to be the major drivers in the spread of HIV and STIs largely in the heterosexual community.

Nevertheless, male-to-male sex, also a key risk, is often hidden and denied.<sup>40</sup>

Therefore, one of the key recommendations<sup>35</sup> is engaging MSM, and those individuals of other “culturally-constructed”, genders in more high quality and participatory research that can be translated into effective prevention programmes.

## Africa

In Africa, the overwhelming scale of the heterosexual epidemic, coupled with the political, social, and cultural barriers against homosexuality, have meant that an MSM-focused response to HIV has been absent across the continent.<sup>41</sup>

It is not surprising that population-level data on MSM in Africa are rare. Same sex relationships are criminalized in 37 out of 54 African countries, and are punishable by death in four of these.<sup>42</sup> In this environment, misconceptions about the potential risks of MSM transmission are easily perpetuated. Another finding across a number of African studies is a high level of bisexual concurrency, with MSM often reporting having both male and female partners.<sup>43</sup>

In summary, scholarly work in recent years has clearly documented that, alongside of the global heterosexual epidemic, most developing countries have significant, if under-recognized, MSM epidemics.<sup>44</sup>

## Prevention of Transmission

Effective prevention of HIV transmission in the context of MSM has several key components:

- i) *Raising the awareness about HIV* acquisition in those at risk, without the use of unnecessarily alarmist language.
- ii) *Education with regards to safer sexual practices.* This includes the use of condoms for anal sex and in the case of oral sex, not taking ejaculate orally. Condom usage within the MSM community in developed countries is relatively high and continues to be one of the most effective methods to prevent HIV transmission. However, even within this community condom usage is becoming less common, with up to 40% of MSM having engaged in unprotected anal intercourse in the past year in certain US cities.<sup>45</sup> Less conscientious safer sex practices may occur in younger MSM (with little direct experience of HIV and AIDS), older MSM (with “safer sex fatigue”), those ending long term relationships and re-engaging in sexual activity, and in those entering new relationships (where the experiences of emotional safety are confused with biological safety). The degree of condom usage within a community is also dependent on the community acceptance of condoms. This can perhaps be influenced by developing prevention programs to develop peer support for condom-protected sexual activity.
- iii) *Reduction in the number of partners.* This is dependent upon cultural norms, but can potentially be influenced by peer education. However, it should be noted that unprotected anal intercourse, even in the context of serial monogamy, may still result in transmission. It should be noted that abstinence

as a method of prevention of HIV transmission has been found to be ineffective in both MSM and heterosexual sexual transmission.<sup>46,47</sup>

- iv) *Avoiding sexual contact* in areas involving open wounds, ulceration and recent dental work.
- v) *Easy access to free, confidential HIV testing*, with those at risk encouraged to undergo this frequently. Potential barriers to this include possible legal ramifications of not disclosing one’s status to potential partners and lack of confidentiality regarding results.
- vi) *Regular testing and prompt treatment of STIs*, particularly Genital Ulcerative Diseases (GUDs) such as HSV, syphilis and lymphogranuloma venereum. GUD increases risk of transmission when this occurs in the HIV co-infected person, and increases the risk of transmission to the HIV negative person via increased viral shedding, and via disruption to the mucosal integrity and/or recruitment of HIV-susceptible inflammatory cells. The rates of GUD are higher in MSM compared to the general population. For example, HSV2 seroprevalence is estimated to be 25–50% in MSM and higher in MSM with HIV positivity (50–70%). Among men who have sex with men (MSM), reported seroprevalences of HSV2 vary as a marker of HIV status: high (80%) prevalences are observed among those co-infected with HIV, while lower (20–50%) seroprevalences are reported for those not infected with HIV.<sup>48,49</sup>
- vii) *Routine testing:* The Centers for Disease Control in the USA currently recommend a policy of routine testing for HIV in STD clinics, emergency departments, hospital wards and physician offices, to try and identify a greater percentage of HIV infected individuals. Such identification would mean more infected people could be reached with safe sex education, and treatment, and would hopefully significantly decrease transmission and the number of new infections. This policy however has not been significantly implemented due to physicians discomfort with offering the test and the lack of reimbursement for routine testing.
- viii) *Early initiation of ART.* From a public health perspective, lowering HIV plasma viral load may lead to a community reduction of transmission, although undetectable plasma viral load does not mean zero risk of HIV transmission. Cases of transmission of HIV when the viral load is <1000 copies/mL have, however, rarely been reported. Population modelling has demonstrated the theoretical feasibility of such an approach.<sup>50,51</sup> There has even been a suggestion<sup>52</sup> that condom usage can be dispensed within discordant couples, where the HIV infected partner has consistent plasma virological suppression on ART. In response to this there is a Swiss consensus statement asserting that people with HIV infection receiving effective antiretroviral treatment (i.e. with undetectable HIV viral load) and without an STI, cannot transmit HIV through sexual contact.<sup>53</sup> A recent consensus statement by the

Australasian Society for HIV Medicine (ASHM), the National Centre for HIV Epidemiology and Clinical Research (NCHECR), Australian Federation of AIDS Organisations (AFAO), and the National Association of People Living with AIDS (NAPWA)<sup>54</sup> strongly cautions against HIV prevention based solely on ART. One of its key recommendations is to encourage further research into HIV transmission, including the role of co-infection with other STIs

- Mathematical modelling demonstrated that risk of HIV transmission in heterosexual partnerships in the presence of effective antiretroviral treatment is low, but not zero. While among male homosexual partnerships the risk transmission is high over repeated exposures.<sup>55</sup>
- However, dispensing with condoms in the presence of HIV plasma viral suppression has not been validated in a MSM population. With increasing evidence of the benefits of earlier treatment of HIV infection in terms of reducing both AIDS related and non AIDS related co-morbidities, there is a developing convergence to treat HIV at diagnosis with the additional benefit of assisting in the reducing HIV. So far this is only theoretical.<sup>56</sup> However, studies are being developed in the United States and elsewhere to formally evaluate this concept by actively treating all of those identified with HIV infection in a community employing routine testing. One such study funded by the National Institutes of Health (NIH) and the US Centers for Disease Control and Prevention will start this year in Bronx, New York, and Washington DC, and will compare outcomes with four matched US cities.<sup>57</sup> The initial study will primarily test the feasibility of such an approach. If successful, it is hoped that future studies will more formally assess the efficacy of widespread and early antiretroviral therapy in eradicating HIV transmission in large populations.<sup>58</sup>

- ix) *Postexposure prophylaxis.* The use of antiretrovirals within 72 hours of potential occupational exposure to HIV is now well-established, and its value is being explored following sexual and injecting encounters. However, the cost, potential toxicities and concerns regarding the encouragement of further risky behaviors has so far limited its deployment. Nonetheless, it does potentially provide an opportunity for risk reduction counselling.
- x) *Pre-exposure prophylaxis.* The use of antiretrovirals (either topically or systemically) before sexual intercourse, or continuously in high risk individuals, for prevention, is currently being researched, but many express concerns that such a program could lead to less condom usage and, if used intermittently, could lead to high levels of ARV resistance to the ARVs used.

NGOs and community organizations frequently have grass roots contacts and experience within affected communities. They are thus able to shape messages that encourage practices which

reduce HIV transmission in language and images which resonate with the specific target group. They may also have a role in the distribution of condoms and water based lubricants at places where MSM meet. The use of NGOs may allow politicians to distance themselves from appearing to support activities which, while evidence-based and effective prevention strategies, are disapproved of by vocal sections of their electorate.

To deliver effective and reliable messages on methods of reducing HIV transmission in MSM populations, the engagement of the community is essential. This allows information to be given in a culturally appropriate, non judgemental manner which addresses the needs of the particular community. The ability to engage with the MSM community and provide these messages is often affected by local moral forces in the form of religious prohibitions, social discrimination and legal restrictions. In some developing countries, those distributing information on safe sex practices and providing condoms and lubricants, have themselves been targeted and subject to criminal sanctions. Measures to decriminalise MSM sexual activity, reduce stigma against MSM, and provide health services and education, can be an important method of combating HIV in the communities and countries affected.<sup>7</sup>

## Management of HIV Infection

The principles of management of HIV infection in the general population also apply to the management of HIV in MSM. For individual patients, the aim is to assess their suitability for ART, mainly on the basis of clinical status, CD4 T lymphocyte count and viral load.

Treatment guidelines worldwide increasingly favour earlier initiation of antiretroviral therapy in HIV-infected individuals.<sup>59–62</sup> The benefits conferred by early treatment are substantial, and include more successful immune reconstitution; lower mortality; lower risk for cardiovascular disease, malignancies, and other complications; improved outcomes of certain HIV-related conditions; slower progression of hepatitis B and C co-infection; attainment of higher CD4 counts on treatment; and lower rates of treatment side effects and HIV drug resistance. The current consensus is to initiate treatment before CD4 levels drop below 350 cells/ $\mu$ L.

ART typically consists of combination therapy involving three drugs, most commonly two nucleosides/nucleotides, with a non nucleoside or a boosted protease inhibitor. Success of therapy is measured by achievement and maintenance of plasma HIV RNA suppression. Consistent adherence is crucial to success, although there are a number of other factors that should also be considered.<sup>63</sup>

## GENERAL MEDICAL MANAGEMENT ISSUES

Evidence accumulated from large cohort studies in developed countries reveal that with combination antiretroviral therapy, mortality and morbidity in HIV infection improves with significant falls in progression to AIDS.<sup>64,65</sup> Mortality from AIDS

and non-AIDS co-morbidities such as cardiovascular, hepatic, renal disease and cancer was higher in the presence of HIV viraemia found during treatment interruptions in the SMART study.<sup>66</sup> Improved survival has led to an increasing age of Western HIV cohorts, and the normal diseases associated with ageing are found at an earlier age in HIV positives. The contributing factors for accelerated ageing include inflammation from low level HIV viremia and immune dysregulation, lifestyle factors such as smoking, alcohol and drugs, co-infections such as hepatitis B and C, and possibly toxic effects of antiretroviral therapy.<sup>67</sup> While prognosis has improved substantially over the years, particularly for those on therapy where CD4 count could be durably increased to normal levels, expected lifespan is expected to be shortened by at least 10 years compared to the average population.<sup>68,69</sup> The implications of ageing for MSM with HIV who are part of a particularly youth-orientated culture are profound and largely unexplored.

Depending on the age of the MSM, a number of general health considerations should be considered, regardless of the HIV status of the man. These include screening for cancers of the prostate, testes and colon, together with cardiovascular assessment. However, it should be noted that access to screening services may be negatively impacted because of some of the issues and challenges related to culturally sensitive care for gay men discussed above.<sup>60</sup> Regular exercise should be encouraged for cardiovascular health, but some men may also require advice regarding the consumption of anabolic steroids and dietary supplements. Excessive weight may be associated with a number of health problems, including diabetes, hypertension, and ischaemic heart disease.

Depression and anxiety appear to affect MSM at higher rates than in the general population,<sup>70</sup> an effect that may be compounded by social isolation and HIV infection. Adolescents and young MSM may be at particularly high risk of suicide because of these concerns. Culturally sensitive mental health services targeted specifically at MSM may be more effective in the prevention, early detection, and treatment of these conditions.

### SPECIFIC ISSUES FOR HIV-INFECTED MSM

Table 87.1 summarizes some of the common challenges faced in the management of HIV positive MSM.

#### Hepatitis A (HAV)

Improving levels of sanitation in many countries in the last two decades have led to a fall in childhood infection, with a concomitant rise in adults susceptible to symptomatic disease and outbreaks. HAV is mainly transmitted through the fecal-oral route. There have been numerous reports of HAV outbreaks among MSM, including in Australia.<sup>71</sup> In Europe, HAV transmission among MSM is endemic. A recent molecular epidemiologic study revealed that 10 HAV outbreaks among MSM in 7 European countries between 1997 and 2005 actually represented one large outbreak among interconnected MSM communities.<sup>72</sup> In the general Australian population the

**Table 87.1:** Common Conditions of HIV-Positive MSM

Condition	Examples
Common conditions of all HIV-infected adults, regardless of method of acquisition	<i>Pneumocystis jiroveci</i> pneumonia and other opportunistic infections, tuberculosis, nephropathies, lymphomas, and treatment-related toxicities
Age-related conditions	Especially in developed countries where widespread use of ARV has resulted in extended life expectancy, for example cerebrovascular disease
Intra-anal and perianal sexually transmitted infections	Condyloma acuminata (anogenital warts) <i>Treponema pallidum</i> (syphilis) <i>Neisseria gonorrhoeae</i> <i>Chlamydia trachomatis</i> Herpes simplex virus types 1 & 2 Lymphogranuloma venereum Tropical ulcers
Sexually transmitted gastrointestinal conditions	Hepatitis A <i>Entamoeba</i> spp. (especially <i>E. histolytica</i> ) <i>Shigella</i> spp. <i>Campylobacter</i> spp. <i>Cryptosporidium</i> spp. <i>Giardia duodenalis</i> <i>Enterobius vermicularis</i> <i>Strongyloides</i> <i>Rectal spirochaetosis</i>
Other common anorectal conditions	Perianal dermatitis Haemorrhoids Abscesses Fissure Fistulae Anal laxity Rectal prolapse
Tumours resulting from STIs	Kaposi's sarcoma, anal cancer
Associated with common risk activities	Hepatitis B & C (from recreational drug use and sexual transmission)
Psychological and psychiatric morbidities	Potentially exacerbated by stigma, ostracism and a direct effect of HIV in the CNS. May be compounded by recreational drug use

Further details of some of these conditions are given below.

seroprevalence is 41%,<sup>73</sup> whereas in a recent cohort of MSM it was 68%,<sup>74</sup> a figure that was thought to represent higher vaccination rates, rather than infection. Adults infected with HAV are more likely to develop icteric hepatitis, although mortality remains generally very low. An interaction with HIV has not been described, even in immunocompromised patients. The rare circumstances in which HAV infection has a significant mortality is when it occurs in older people (>40 years), or those with chronic liver disease, such as that due to HCV, HBV, or alcohol. All MSM should be vaccinated against HAV if antibody negative on screening.

## Hepatitis B (HBV)

HBV is very efficiently transmitted sexually during heterosexual and homosexual contact. Before the HIV/AIDS epidemic, up to 50–70% of homosexual men had serological evidence of past or present infection with HBV.<sup>75</sup>

However, there is evidence that the incidence of HBV infection in gay men has decreased markedly since the early 1980s, associated with the adoption of safe sex, and the advent of an effective HBV vaccine. For example, in Australia, the seroprevalence of core antibody has decreased from 61% in 1982 to 38% in 1991 to 19% in 2004.<sup>74,76,77</sup>

Moreover, in an observational cohort of 2218 HIV-infected MSM (mostly) on antiretroviral therapy in 2003, the seroprevalence was only 4.8%.<sup>78</sup> However, HBV transmission is endemic among HIV-infected MSM in Europe.<sup>79</sup> Vaccination against HBV is highly recommended for all MSM, although it is less effective in HIV-infected individuals.<sup>80</sup> Post-vaccination testing for HBV surface antibody is recommended, and vaccine non-responders should undergo repeat immunization with a full series. The benefit of double dosage, the appropriate strategy for HIV-infected patients with isolated core antibody, and the timing and number of vaccinations in persons with advanced immunosuppression on highly active antiretroviral therapy remain controversial.<sup>81</sup>

The diagnosis of HIV/HBV co-infection is usually made via detection of hepatitis B surface antigen (HBsAg), but since immunodeficient individuals may be negative, it is recommended that they also be tested for the presence of anti-core antibody (anti-HBc). If either is present, patients should be evaluated for active HBV replication, using an assay for HBV DNA.

The importance of HIV/HBV co-infection lies in the profound effects of HIV on the natural history of HBV infection; it is not cleared as efficiently; the prevalence of chronic HBV is 25%, compared to 3–5% in HIV-seronegative MSM with HBV.<sup>82,83</sup> Presumably, this could have an important effect on the epidemiology of HBV.<sup>84</sup> Despite the high levels of HBV replication, co-infected patients have significantly lower serum alanine aminotransferase levels than those with chronic HBV alone, and yet progression to cirrhosis is more common.<sup>82</sup>

In contrast to the effect of HIV on HBV infection, most studies have not detected a significant effect of HBV infection on the clinical course of HIV infection,<sup>84,85</sup> or on the rate of antiretroviral treatment change.<sup>78</sup>

The management of HIV/HBV co-infection is complex, and best left to experts in the field. Sustained suppression of serum HBV DNA to below the level of detection by the most sensitive assay should be the goal of therapy and at present treatment of HBV in this setting is life-long. Close monitoring is necessary to detect failure or hepatic flares, particularly following initiation of combination antiretroviral therapy (cART). It is worth remembering that severe hepatotoxicity occurs in up to 10% of all patients commenced on cART, and that all antiretrovirals

have been associated with abnormal liver function, particularly ritonavir, nevirapine, and tipranavir, whose use should be avoided. Most of the drugs used to treat HBV infection (eg lamivudine, telbivudine, adefovir, tenofovir, entecavir) have some *in vitro* activity against HIV, and both viruses can be treated with a simplified combination of drugs (usually containing tenofovir and emtricitabine). A more detailed discussion on management can be found elsewhere.<sup>86,87</sup>

## Hepatitis C (HCV)

The sexual transmission of HCV has generally been considered to be inefficient as estimated by cross-sectional studies in populations usually considered to have a high prevalence of STIs. In a national survey of 17,000 GUM clinic attendees in London in 1995,<sup>88</sup> only 1% were positive for HCV. In a cohort of 1038 homosexually active men in Sydney between 1984 and 1989,<sup>89</sup> 7% were seropositive for HCV; moreover, being positive was associated with IDU and/or HIV, but not sexual behaviour.

However, in a series of case reports and large clusters, it is apparent that there has been a recent epidemic of HCV among HIV-infected MSM in Europe and Australia.<sup>90–93</sup> The vast majority of cases deny IDU, but most have been associated with high risk sexual behaviours that are more likely to be associated with anal trauma; hence they have been designated “per-mucosal”. 250 strains from Europe and Australia were subjected to a molecular phylogenetic study.<sup>94</sup> A “molecular clock” analysis suggested that the majority of transmissions (85%) occurred since 1996; temporarily then, this epidemic coincides with the introduction of highly active antiretroviral therapy (HAART), and some increases in high risk sexual behaviours. It is speculated that apart from possible impaired immunological control of HCV and/or increased viral load in semen,<sup>95–97</sup> the largest risk factor in these cases is an increase in high risk sexual behaviours, including large numbers of partners, seroconcordant sexual partnering (sero-sorting), disinhibition with recreational drug use etc. These speculations have recently been extensively reviewed.<sup>98</sup>

Most MSM with HCV report a combination of various, potentially high risk, sexual and drug practices. The interaction between sex and drugs is complex, and many of these factors are highly correlated and difficult to disentangle. Intranasal and rectal drug use in itself could favour HCV transmission via shared contaminated implements. It is more likely however, that the association with drug use reflects residual confounding: unmeasured sexual risk behaviour due to disinhibition and sexual arousal. Based on current knowledge, sexual transmission of HCV is probably mediated by factors such as traumatic sexual techniques and ulcerative STIs that may cause mucosal damage in the rectum. However, it is striking that the recent outbreak almost exclusively affects HIV-infected MSM; the HCV incidence in HIV-negative MSM is still low, indicating that these men remain largely unaffected. Therefore, it is also likely that the

immunological changes associated with HIV are contributing to the changing epidemiology. First, HIV perturbations of the GI immune system have become a major focus for the immunopathogenesis in HIV, so it is conceivable that defects in mucosal immunity are also facilitating permucosal transmission of HCV.<sup>99</sup>

In addition, defects in cell-mediated responses are associated with reduced HCV clearance, and higher HCV viral loads in serum and semen.

In Sydney, Australia, the most recent estimates of HIV/HCV co-infection are 9.39% and 12.8%, and come from a cohort of HIV-infected men, and an observational database of HIV-infected persons on treatment.<sup>78,100</sup>

The major impact of HIV/HCV co-infection on the natural history of HCV is the acceleration of liver disease progression.<sup>101</sup> Co-infection is associated with a higher mortality than mono-infection with either virus alone. Prior to the HAART era, the high mortality from AIDS-related causes predominated, and masked any other causes for mortality. However, as effective therapy for HIV became available and AIDS-related mortality declined, liver-associated mortality emerged as the second most frequent cause of death, especially in those with co-infections, often with excessive use of alcohol as a cofactor. Co-infection is associated with lower rates of spontaneous HCV clearance, accelerated liver disease, and less favourable disease outcomes. However, it has recently been shown in an Australian study that treatment outcomes can be improved if started early.<sup>102</sup> The diagnosis of HCV infection is made by the detection of HCV antibody and the detection of HCV RNA by polymerase chain reaction (PCR) in serum. HCV genotyping is important, as some genotypes are relatively resistant to therapy and prolonged treatment is required. Decisions regarding management are complex, and include drug toxicities, patient preference, and adherence. In general, people with significant immunodeficiency should be treated with cART first; others with preserved immune function can receive treatment for HCV first. In HIV-negative individuals, acute HCV is almost always treated with PEG monotherapy; in HIV-positive individuals, there has been greater variation, with a general trend towards the use of combination therapy with ribavirin, although there is little evidence to support this, and it may add significant risk of toxicity and drug interactions. In the future, there is likely to be a paradigm shift using HCV protease and polymerase inhibitors.

## Syphilis

After an initial decline in the 1980s, coincident with the advent of AIDS, syphilis has emerged as a major problem in the 1990s in MSM in Australia,<sup>103,104</sup> United States,<sup>105</sup> Europe,<sup>106,107</sup> China,<sup>108</sup> and other less developed countries.<sup>109</sup> It has disproportionately affected MSM with HIV-infection; in Australia the rate in homosexual men with HIV is 5–10 times higher than in HIV-negative men. The reasons for this

are unclear; early syphilis is transiently associated with low CD4 counts and a high viral load, these return to baseline levels with treatment.<sup>110</sup> Many investigators have suggested that it reflects higher levels of unprotected sexual activity among gay men with HIV-infection.<sup>12,111</sup>

There are higher rates of asymptomatic syphilis, and higher rates of relapse if untreated; moreover individuals with HIV are more likely to present with secondary syphilis than those without HIV.<sup>112</sup> Oral sex is established as an efficient method of transmission.

Notwithstanding the conventional use of serology, with its small but significant numbers of false positives (due to polyclonal B-cell stimulation) and false negatives, (due to the prozone phenomenon, or lack of an immune response), a significant number of laboratories are utilizing PCR techniques for lesional syphilis.<sup>113,114</sup>

Neurological involvement of syphilis in HIV co-infection manifesting as acute syphilitic meningitis, ocular disease and more rapid progression to tertiary syphilis, has been found more frequently than in syphilis mono-infection, particularly with plasma RPR  $\geq 1:32$  or CD4 count  $\leq 350$  cells/ $\mu$ L.<sup>115,116</sup>

Re-infection is possible and is detected by an increasing non-treponemal assay titer.<sup>117</sup> Three-monthly testing is recommended for persons at high risk,<sup>118</sup> and modelling exercises have shown this period to be optimal for gradually reducing the epidemic; these recommendations will likely be extended to all HIV infected men. Contact tracing is very important; any contact within 90 days of early syphilis should be presumptively treated with benzathine penicillin.

Other aspects of the diagnosis and management of syphilis in HIV-infected individuals are covered comprehensively in Chapter 84.

## Lymphogranuloma Venereum

Lymphogranuloma venereum (LGV) has been recognised as an endemic cause of genital ulcer disease in Africa and Asia for many years. However, since 2003, it has emerged in Western countries as an infection of significance in MSM, particularly those with HIV infection. It has the potential to enhance HIV and HCV transmission because of its ulcerative and inflammatory nature. In addition to its association with HIV, LGV infection is also associated with the presence of other STIs, anal enema use, unprotective anal intercourse, use of sex toys, and fisting. It is caused by infection with *C. trachomatis* serovars L1, L2, and L3, particularly L2b and diagnosis requires biovar specific testing of *C. trachomatis* positive specimens. Unlike regular chlamydial infection (caused by serovars D-K), LGV is associated with a clinically more aggressive course, symptomatic proctitis, invasive infection with a predilection for regional lymph node involvement, and in some cases tissue inflammation resulting in fistula formation, and systemic symptoms may occur. Involvement of inguinal or femoral nodes may result in suppurative infections called “buboes”. Recommended therapy is 21 days of doxycycline 100 mg bd.<sup>11,119–122</sup>

## Increased Risk for MRSA Skin and Soft Tissue Infections among HIV-Infected Persons

HIV-infected persons have an elevated risk for both MRSA (methicillin-resistant *Staphylococcus aureus*) colonization and infection. Recent studies from USA suggest that patients with HIV have an 18-times higher rate of MRSA infections than the general population.<sup>123</sup> Clinical manifestations mirror those seen in the general population; most patients present with skin and soft tissue infections (SSTIs) including furuncles, abscesses, and/or cellulitis. Complicated disease may also occur, including necrotizing soft-tissue infections, fasciitis, bacteremia, and endocarditis.<sup>124–126</sup>

The reasons for the increased risk for MRSA infections among HIV patients is unknown, but it may be related to an increased use of antibiotics in this population (e.g. beta-lactam antibiotics), intravenous drug use, high-risk sexual behaviours, and poor immune status. In addition to the higher risk for MRSA infections, HIV-infected persons also appear to have a high risk for recurrent SSTIs after an initial MRSA infection; this may be due to persistent colonisation, e.g. nasal or even perineal, carriage.<sup>127</sup> Studies involving novel carriage sites as well as the effectiveness of decolonisation strategies are needed.

The management is conventional, namely incision and drainage, and treatment with an antibiotic that may need to be modified after susceptibility testing. Initial choices include cotrimoxazole, doxycycline, clindamycin or intravenous antibiotics such as vancomycin. Given the high risk of recurrence, patients should be counselled to present early with any new skin lesion that may represent MRSA.

## Circumcision and Male-to-Male Transmission

In 2006, Drain<sup>128</sup> evaluated relationships between male circumcision (MC) prevalence, Muslim and Christian religion, and seven infectious diseases using country-specific data among 118 developing countries. In multivariate analyses among non-sub-Saharan African countries controlling for religion, higher MC prevalence was associated with 8.94-fold decrease in the adult HIV-prevalence among countries with primarily heterosexual HIV-transmission, but not, as expected, among countries with primarily homosexual or injecting drug use HIV-transmission.

However, analyses of available observational and cohort studies of MSM<sup>23,24,26,129–131</sup> revealed insufficient evidence that male circumcision protects against HIV infection, or other STIs.

The absence of clear evidence of a protective effect of circumcision against HIV and other STIs in MSM may be the consequence of the failure of past studies to stratify analyses by subjects' anal sexual role. MSM can practice exclusively insertive anal sex, exclusively receptive anal sex, or not engage in anal intercourse at all. Because receptive anal sex

poses the greatest per-contact risk for HIV acquisition<sup>132</sup> and circumcision would not affect the risk through being exposed to HIV as a receptive partner, it has been hypothesized that the protective effects of a circumcision would vary, based on a man's anal sexual behavior. Men who are primarily the insertive partner during anal intercourse would benefit most from circumcision, men who were versatile during anal intercourse would receive some protection, and those who were primarily the receptive partner would receive little or no protection.

### Summary

- MSM with HIV are over-represented but under-recognized in many countries. However, most MSM do not have HIV.
- MSM activities are illegal in many countries contributing to stigma, failure to seek healthcare and reluctance to disclose risk activities.
- Targeted prevention strategies are most effective that include MSM community involvement and those that reduce stigma and discrimination.
- Higher rates of co-morbidities including STIs, drug and alcohol issues and mental illness are found in MSM with HIV.
- Medical services providing confidential and supportive care attuned to the needs of MSM facilitate disclosure and enhance capacity to control the epidemic.

# HIV in Blood and Blood Product Recipients

Roger J. Garsia

88

## Current Scale of Medically Acquired HIV Infection

Concerns about the potential for donor derived blood products to transmit chronic viral infection initially centered on hepatitis B virus in the mid 1970s and after introduction of screening for hepatitis B surface antigenemia attention shifted to non-A, non-B hepatitis infection by the end of that decade.<sup>1</sup> HIV contamination of the therapeutic blood and tissue supply in the late 1970s and early 1980s was unrecognized initially,<sup>2</sup> and led to a serious and widespread epidemic of medically acquired HIV infection.<sup>3–6</sup> Identification of antibodies to Lymphadenopathy Associated Virus (LAV, later renamed HIV) in those with AIDS, and in seemingly healthy carriers,<sup>7</sup> was pivotal in provoking action to protect the global blood supply. During the 1980s most reports of screening in blood product exposed hemophiliac cohorts, conducted in developed and medium-income countries showed HIV antibody prevalence of 70% or more in the hemophiliacs who had been the greatest users of coagulation factors.<sup>6,8</sup> At a sub-population level, the severity of coagulation factor deficiency in developed countries generally correlated with rates of cumulative blood product exposure, and consequently HIV transmission risk.

In most cases infection was sub-clinical, without what is now recognized as HIV seroconversion illness symptoms. Consequently, the diagnosis of infection in HIV-exposed individuals was not made reliably until highly specific serology became widely available,<sup>8</sup> and cohorts of blood product recipients were screened for the synonymous HTLV-III/LAV/HIV in lookback programs undertaken as an urgent priority in the mid 1980s.<sup>9</sup> In the intervening period, secondary transmissions to sexual partners were not rare, and the consequences of HIV infection devastated many families and catalyzed international action against discrimination. Measures operating at many levels were taken to protect the blood supply from ongoing contamination. Principally, safety was improved by donor selection, antibody-based screening for HIV, and then post-collection virus inactivation procedures of the blood products. Heat and detergent-based virus inactivation treatment was only

feasible for a limited range of plasma-derived products to reduce the risk of viral transmission,<sup>10</sup> and there were no chemical or physical treatments suitable for decontaminating whole blood, or cell products derived from blood.

## Impact of Donor Screening with High Sensitivity Antibody Tests

In those developed countries which instituted rigorous donor selection followed by serological screening for HIV antibody, new HIV infections in recipients of blood, fractionated blood products, or tissues became rare.<sup>11</sup> Confidence in the safety of blood has resulted in high rates of growth of blood product use in developed countries, for example, the number of hospital admissions involving blood transfusions more than doubled (140% increase) over a 10-year period 1997–2007 in the US<sup>12</sup>; currently in that country, in 2010, it is estimated that over 16 million separate donations will be collected from 9 million plus donors. Although data are often unavailable for low-income countries, the trends in usage are upwards. Coping with the escalating costs of ensuring a safe blood supply has been a challenge for many jurisdictions. Many poor countries were not able to introduce serological testing of individual donors till the 1990s, and, even some 25 years after availability of HIV screening serologically, not all countries have quality-assured screening for 100% of donations<sup>13</sup>; WHO data show many nations are still dependent on paid donors for plasma and blood supplies. Furthermore, many blood banks do not use assays capable of detecting HIV antigenemia and rely only on detecting antibody to HIV, a testing algorithm that leaves the blood supply vulnerable to an approximately three-week window period of pre-seroconversion infectivity from donors with newly acquired HIV.

More than a quarter of a century after the availability of HIV serology, occasional cases of very long standing transfusion-acquired HIV, whose acquisition can be traced back to the era prior to blood donor screening, are still being diagnosed.<sup>14</sup> Despite the many advances in diagnostic HIV testing and the use of NAT technology, which shortens the average screen-

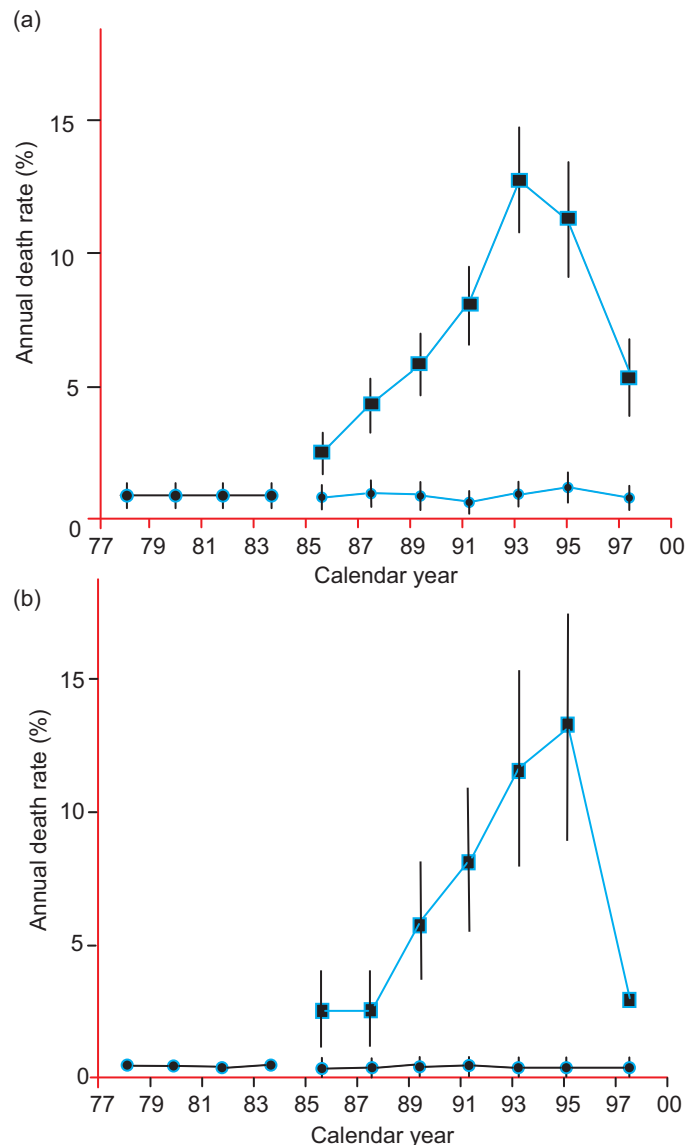

negative window period to about 10 days, HIV transmission still occasionally occurs from blood products of donors whose HIV infection has eluded the most sophisticated of modern screening tests.<sup>15</sup> Awareness of the potential for virus screened blood products to transmit infection remains high among medical practitioners in most countries, particularly those with paid donors and a high HIV-prevalence in heterosexual populations, including intravenous drug users. Unfortunately the general population has a much poorer understanding of the risks inherent in transfusion. Internationally significant efforts are continuing to promote the importance of quality-assured universal testing of all donated units of blood. However vigilance in excluding virus screen-negative, potentially contaminated units, based on behavioral questionnaires of donors, is still an important though controversial element of success in containing the spread of HIV by blood and tissue products.<sup>16</sup>

The vast majority of cases of medically transmitted HIV were diagnosed in the decade immediately following their acquisition, as a result of high rates of uptake of the newly developed first-generation enzyme linked immunosorbent assay for HIV antibodies used as screening tests from the mid 1980s.<sup>17</sup> Many campaigns urging those who were blood product exposed to present for testing were directed at hemophiliacs and other frequent transfusion recipients. From lookback campaigns came important data unequivocally linking the development of HIV infection, and in some cases AIDS, in recipients with carriage of the same virus in donors.<sup>18</sup> One well studied transmission cluster provided evidence that some donor-recipient pairs progressed similarly slowly when infected with naturally attenuated virus deficient in the *nef* region of the HIV genome.<sup>19</sup>

### Altering Natural History of HIV in Medically Acquired HIV with Antiretroviral Therapy

From the time of available HIV serology the medical profession was exhorted to seek out possible recipients of contaminated blood sourced material.<sup>20</sup> Thus many of those diagnosed with HIV after screening were asymptomatic, but sufficiently immunodeficient by CD4 T cell numerical criteria, to warrant antimicrobial prophylaxis of opportunistic infection and early access to antiretroviral therapies in clinical trials or compassionate access programs. As new agents and classes of antivirals emerged from the pharmaceutical industry's drug-development programs, long infected, highly drug experienced patients, such as those with blood product related HIV, were frequently among the first to use them. The success of combination antiretroviral therapies has led to the current situation, whereby the survivors of transfusion and transplantation related HIV are now, in the second decade of the 21<sup>st</sup> century, almost exclusively of adult age, and highly antiviral-treatment experienced; many have been HIV infected for over 25 years (Fig. 88.1).<sup>17</sup> With the demographic features of very long duration HIV, and facing a significantly shortened life expectancy, they present the treating clinician with a complex set of management considerations.

**Fig. 88.1:** The impact of HIV on UK hemophilia cohorts. Age standardized annual male death rate for all UK hemophiliacs whose hemophilia was severe (a) or mild/moderate (b) and whose HIV status was unknown in 1977-1984 (circles) or known in 1985-1999 to be HIV positive (filled rectangles) or HIV negative (filled circles). *Source:* Darby SC, Kan SW, Spooner, et al.<sup>17</sup>

Those who acquired HIV at a very young age, whether from contaminated blood products or from vertical transmission, displayed variable patterns of progression to immunodeficiency and AIDS. A subgroup of these never reached their teenage years.<sup>20</sup> In contrast, those infected during teenage and early adulthood tended to have a better prognosis than older adults, and many more of them have survived, supported by access to effective HAART from the mid 1990s. Many have reached middle age, where they face the impact of ageing coupled with the impact of the biological effects of HIV and its treatment. Long-term survivors now form a large proportion of the category of those currently living with HIV acquired from blood products.<sup>17</sup>

## Co-infection with HIV and Hepatitis Viruses

Data emanating from hepatitis C screening of national and international cohorts of HIV positive hemophilia patients revealed the high rates of hepatitis C virus co-infection,<sup>21</sup> and in some centers triple infection was documented with both hepatitis C and hepatitis B complicating HIV in a small proportion of patients.<sup>22</sup> Thus medical management in transfusional HIV has been frequently complicated, and not infrequently dominated, by the co-morbidity of chronic viral hepatitis.<sup>23</sup> Furthermore, many of the HIV and hepatitis infections in hemophiliacs were acquired from large batch donor-pooled products. Consequently they were at risk for acquiring multiple quasispecies of HIV, and/or multiple genotypes of hepatitis viruses.<sup>24</sup> On the other hand, cell product recipients, other than those with need for repeated transfusion, frequently had single donor -sourced virus infection, and most escaped both HIV and the hepatitis viruses, or acquired just one type of infection. Many of the latter group were, however, afflicted by serious illnesses, often fatal, at the time of transfusion; therefore, studying their subsequent course has generally not provided the depth of insight into HIV that the larger hemophilia patient cohorts have provided.

## Treatment Approaches

Except in the small number of HIV-infected subjects (approximately 2–5% ) who contain the HIV virus at very low levels, generally less than 1000 RNA copies/ml, and in whom CD4 T cell decline is slow or absent, relentless decline in immune competence is the norm, with a rate of decline correlated with HIV RNA viral load, irrespective of the mode of acquisition of the virus.<sup>20,25</sup> By contrast, those taking up treatment with antiretrovirals experienced dramatic immune reconstitution, and a corresponding improvement in prognosis, when the multi-agent HAART regimens were used.<sup>26</sup>

Fortunately, the principles of therapy for HIV in transfusion-acquired cases are broadly the same as those in the sexually acquired cases. A note of caution is that the newest agents targeting the HIV integrase enzyme, or co-receptor binding, were not specifically trialed in populations with congenital coagulopathies, such as hemophilia, hemoglobinopathies, or hemolytic diseases. Close scrutiny of post-marketing adverse event reports may reveal concerns regarding administration of specific new agents in future. Conversely, product warnings may provoke an overly pessimistic view of the likely side effect profile in these populations. On balance, careful planning of regimens is vital, and enhanced surveillance for adverse metabolic, hepatic, and bleeding side effects is required, but the need for treatment can be compelling, and often justifies proceeding with use of new agents, albeit cautiously. Some specific treatment issues warrant special consideration as listed in Table 88.1.

### BLEEDING

For patients with congenital bleeding disorders who require cART, it is important to establish whether the intended combination

**Table 88.1:** Treatment Considerations in Medically Acquired HIV Cases

1. Bleeding
2. Hypotension/risk of falls
3. Seizures
4. Anemia
5. Thrombocytopenia
6. Liver function
7. Induction of inhibitors
8. Induction of Immune Reconstitution Syndrome (IRS) involving hepatitis C and hepatitis B
9. Arthropathy and arthritis
10. Pre-existing bone demineralization
11. Unreliability of certain clinical and laboratory indicators
12. Fertility/heterosexual issues
13. Pain management drug interactions and use of NSAIDs
14. Vaccination
15. Surgery

has the potential to cause adverse effects on platelet function. For example, a number of reports have pointed to increased bleeding risk in patients with hemophilia taking Tipranavir, a modern protease inhibitor, which has also been reported to impact adversely on liver function in some patients. An observed effect of Tipranavir on platelet activation may be an explanation.<sup>27</sup> Careful monitoring can only partially offset idiosyncratic risks from antiviral therapies.

### HYPOTENSION AND RISK OF FALLS

HIV frequently causes subtle impairment of motor function, ranging from features seen in mild neurocognitive disorders to severe forms usually with HIV-associated dementia and cerebral atrophy on MRI examination of the brain.<sup>28</sup> Neurocognitive disorders can become the dominant determinant of HIV prognosis in those affected. The progression from minor abnormalities to the fully established manifestations of HIV-associated severe neurocognitive damage is usually slow and its progression appears to be slowed by antiretroviral therapy, though some cases progress despite cART.<sup>29</sup> Dramatic improvements in cognition after commencement of antiretroviral therapy have been documented in many individual case reports and larger retrospective analyses.<sup>30</sup> A minority of patients with hemophilia and HIV have experienced prior intracerebral bleeding with residual encephalomalacia, with its physical, neurocognitive, and seizure-triggering consequences. Fortunately, HIV-associated neurocognitive disorders are not overtly more prevalent in those infected with HIV in childhood and adolescence, but studies on these issues are sparse, as prior traumatic cerebral damage and the consequences of hemophilic arthropathy on balance and gait greatly complicate neuropsychometric studies and assessment of motor function.

In the management of HIV in patients with hemophilia and those with thrombocytopenia particular attention needs to be paid to ensure that the therapy of HIV and its complications do not produce hypotension or impair coordination leading to falls. This relates particularly to avoidance of overly aggressive management of diabetes/insulin resistance in people receiving cART.

## SEIZURES

Seizures are increased in people with HIV infection, and thus are a serious risk for hemophiliacs and thrombocytopenic patients with HIV, as seizures cause an increased risk of trauma and intracerebral bleeding. Conversely, the development of new seizures in a patient with hemophilia should prompt urgent assessment regarding the possibility of a primary intracerebral hemorrhage. A significant number of patients, particularly those who lived with hemophilia prior to modern therapies, have cerebral scarring, from previous intracerebral bleeding episodes, which may provoke seizure activity. Seizure recurrence should be minimized by anti-epileptics in hemophilia patients who have experienced even a single seizure. Prophylactic anticonvulsants are generally not recommended prior to a first seizure.

## ANEMIA

Establishing the cause of anemia in patients with HIV is often complex and laborious due to:

- (a) dyserythropoiesis due to HIV
- (b) the tendency for macrocytosis in patients receiving some of the nucleoside analogues (in particular Zidovudine)
- (c) altered vitamin needs
- (d) HIV associated risk of neoplasia

The high frequency of neoplasia, including gastrointestinal lymphoma, is seen across all modes of HIV acquisition. Anemia should be investigated when it occurs. The development of hemolysis in a patient with HIV should prompt consideration of the possibility of an occult lymphoproliferative disorder. Autoimmune hemolysis in HIV without underlying malignancy is surprisingly uncommon. Many patients with hemophilia or transfusion acquired HIV are also hepatitis C infected, and may need treatment with Interferon and Ribavirin. The latter can be associated with hemolysis and non-hemolytic anemia.

- (e) toxic hemolysis

In countries with a high prevalence of G6PD deficiency, toxic hemolysis is high on the list of differential diagnoses, and the choice of agents for prophylaxis of *Pneumocystis pneumonia* needs to take this into account. Atovaquone is increasingly finding a role in this setting as it does not carry a significant risk of inducing hemolysis.

## THROMBOCYTOPENIA

Thrombocytopenia in HIV is often multifactorial, and even more so in those with pre-existing hematological disorders. Those cases with an autoimmune basis or those resulting from bone marrow dysplasia generally improve with cART. Immune-mediated severe cases may require treatment with intravenous immunoglobulin, steroids, or occasionally splenectomy which may lead to interference with the ability to monitor the course of HIV due to its elevating effect on CD4 T cells.

Thrombocytopenia in combination with hemophilia and HIV is a particularly threatening situation. The platelet count thresholds for intervention with treatment for thrombocytopenia which apply in non-hemophiliacs, may need to be modified for those with severe factor VIII or factor IX deficiency, particularly if there is concurrent hepatitis C infection further impairing production of other coagulation factors produced by the liver.<sup>31</sup>

## LIVER FUNCTION ABNORMALITIES

The development of abnormal liver function tests in patients with transfusional HIV raises a long list of differential diagnoses. Determining the likely cause requires knowledge about prior vaccination status for hepatitis B and hepatitis A, as both these agents remain as potential blood transmissible, vaccine preventable risks to non-immune individuals. Hepatitis A lacks a lipid coat and therefore is not inactivated by solvent/detergent treatment of coagulation factors. However, the major cause of liver dysfunction in transfusion-acquired HIV is co-infection and activation of either or both hepatitis C and hepatitis B. Most cohorts of blood product recipients with HIV have shown that those who survived the first decade of HIV infection suffered accelerated hepatic damage from hepatitis C or hepatitis B in later years; furthermore, in many cases transaminases have not been significantly elevated during the slow development of cirrhosis. A small but important group of patients have been triply infected with hepatitis B, hepatitis C, and HIV,<sup>32</sup> and their course, if not adequately treated for hepatitis, is particularly problematic. Even those whose hepatitis virus has led to virus induced compensated cirrhosis and who do not have hemophilia experience mortality in excess of 5% per year if HIV infection is present.

Immune recovery with cART is sufficiently robust in many cases to allow safe and effective concurrent treatment of HIV and hepatitis viruses with cART and ribavirin/PEGylated interferon, respectively. Many centers have now reported comparable outcomes in hepatitis C eradication in long standing transfusion acquired HIV/hepatitis C co-infected cases as in a comparable population of patients dually infected through intravenous drug use,<sup>33</sup> but in both groups responses to therapy are inferior to hepatitis C mono-infected subjects with matched genotypes. Biomarker predictors of response to therapy, such as IL28 polymorphisms and levels of pre-treatment IP10, are increasingly being studied in hepatitis C infected subjects; if they or similar markers prove applicable in HIV/hepatitis C co-infection, patient selection for treatment will be greatly facilitated.

In general, hepatitis C in medically acquired co-infection should be treated with standard approaches for HIV/hepatitis C co-infected patients, mindful particularly of thrombocytopenia as a potential complication during interferon therapy.<sup>23</sup> The injections of PEGylated Interferon are generally well tolerated with only minimal bruising, and hemophiliacs do not usually require any supplemental coagulation factor concentrates. A number of studies, including a meta-analysis, have shown superiority of PEGylated Interferon 2-alpha over PEGylated interferon 2-beta in mono-infected patients, though a formal comparison has not

been made with an HIV-hepatitis C co-infected patient cohort such as hemophiliacs.<sup>34–36</sup>

Despite an inferior 5-year survival in HCV and HIV co-infected recipients of liver transplants when compared to HIV-negative hepatitis C infected subjects, worldwide there have been a number of liver transplantations performed for chronic viral hepatitis complicated by cirrhosis or malignancy. Although liver transplant may also provide a lifelong cure of the hemophilia if successfully grafted, infection of the transplanted orthotopic liver with the recipient's hepatitis virus is likely to follow even when vigorous attempts to prevent reinfection are undertaken. Immune reconstitution may provoke a serious flare up in active hepatitis B or hepatitis C, to the point of liver failure developing if hepatitis virus expression in the liver is active during weaning of immunosuppression or immunological reconstitution under the influence of cART. Consequently, those with co-infection by HIV and hepatitis C or HIV and hepatitis B need to be closely monitored during therapy for HIV. A number of studies have shown a high life-time risk of developing cholestatic complications during antiretroviral therapy in transfusion related co-infected patients. These should be managed similarly to other co-infected patients with cholestasis. New agents currently in advanced stages of clinical trials, directed at the hepatitis C protease, show great promise, and have the potential to further improve the success rate of hepatitis C treatment in the HIV/hepatitis C co-infected.<sup>37</sup>

## INDUCTION OF ANTIBODY INHIBITORS TO COAGULATION FACTORS

Initially there were concerns that the high frequency of autoimmune disease in patients with HIV might lead to an increased frequency of development of antibody-mediated inhibitors of coagulation pathway components. Fortunately, this has not happened, and in general, levels of clinically significant inhibitors have not been increased in people with HIV without pre-existing coagulation disorders, nor in those receiving either donor derived, or recombinant factor VIII pharmaceuticals, as treatment for hemophilia. However, patients receiving antiretroviral therapy occasionally develop inhibitors to coagulation, and some reports have viewed this as a manifestation of immune reconstitution syndrome (IRS).<sup>38</sup> Modern approaches involving tolerizing exposure to high-dose coagulation factor, immunosuppression, and cytotoxics to treat antibodies behaving as functional inhibitors, are problematic in HIV, as they damage T cell function, and even use of anti-B cell therapy in HIV adds additional immunosuppression to an already damaged immune system. Nonetheless, serious bleeding due to coagulation inhibitors may require cytotoxic therapy, rituximab (anti-B cell), corticosteroids and other immunosuppressants. Immunoabsorption techniques to remove immunoglobulins have also been reported to be of value in this setting, without the negative consequence on the integrity of the immune system, but they are short term in effect, and need to be supplemented by therapy directed at the underlying autoimmune process; other approaches have utilized coagulation

factors downstream in the coagulation cascade as pharmaceuticals to bypass proximal pathway deficiencies.<sup>39</sup>

## ARTHROPATHY AND ARTHRITIS

Hemophilic arthropathy, and the need for joint replacement for pain relief and to facilitate improved mobility, were fundamental drivers for the high rates of usage of factor VIII concentrates and factor IX concentrates in the early 1980s. When the available clotting factors were recognized to be unsafe, utilization of coagulation factors and surgery rates in hemophilia significantly decreased and have persisted to some extent in recent years in many countries, especially those without access to recombinant coagulation factors. Many patients remain reluctant to undergo high level exposure to coagulation products except in emergency situations. Hemophilic joints are prone to secondary infection both after instrumentation, and from hematogenous spread of bacteria. Early series revealed that salmonella was not uncommon as the causative agent in septic arthritis in HIV infection.<sup>40</sup> Treatment needs to be empiric pending culture, but other organisms found not infrequently include staphylococci, respiratory tract organisms, and gram-negative bacteria.

The development of a septic joint in a patient with hemophilia and HIV should prompt urgent aspiration and bacteriological studies, as the infecting organisms are potentially diverse. In practice, it is generally relatively easy to distinguish by history and examination acute hemophilic hemarthrosis from mechanical injury or sepsis, but acute polyarthritis poses a dilemma, as bacteremic seeding to already damaged joints and/or reactive arthritis may be indistinguishable without joint fluid analysis and culture.

## PRE-EXISTING BONE DEMINERALIZATION

Hemophilic arthropathy often results in wasting of muscles proximal and distal to the involved joints and secondary disuse and further joint injury may follow. Thus is set in train a pathway to non-generalized osteoporosis not uncommonly seen as demineralization of hemophilic patients' bones.<sup>41</sup> Those receiving cART are also susceptible to treatment-mediated further reductions in bone density, associated with low vitamin D levels in some cases. Bone mineral density studies are complex to interpret in those with hemophilic arthropathy, but nonetheless are worthwhile. Frequently, upper limb bone density is more suitable for assessment than hip and femoral density. Supplemental treatment with various anti-resorptive agents, bisphosphonates, calcium, vitamin D, and exercise programs may all have a place in this setting, but at present consensus is lacking as to the appropriate interventions to best deal with HIV-associated osteopenia.

## INTERFERENCE WITH CLINICAL AND LABORATORY TESTS

Hemophilia due to factor VIII or factor IX deficiency results in impaired coagulation *in vitro* as well as *in vivo*, and achieving "clean" serum samples is sometimes problematic with fibrinogen bands commonly present in preparations intended

to be purely serum. This can complicate the interpretation of electrophoretograms and has occasionally led to a misdiagnosis of paraproteinemia. Other clinical tests that may be adversely impacted by hemophilia include tests for the presence of hematuria; not infrequently urinary bleeding is the result of coagulopathy rather than underlying urinary tract pathology.

## FERTILITY ISSUES

Many of the world's surviving patients with HIV acquired from transfusion or coagulation factors are currently in fertile age groups. The genetics of hemophilia have resulted in the bulk of symptomatic cases being male, though occasional female carriers of X-linked genetic disorders are partially at risk. Symptomatic female carriers of X-linked coagulopathic disorders may have acquired HIV from transfusion of coagulation factors or blood, usually in the context of peri-operative treatment. Irrespective of the sex of the HIV-positive person, fertility issues abound in the management of people with HIV.<sup>42</sup> Assisted reproduction techniques are widely used to minimize the risk of transmission to a seronegative woman from a seropositive male. The converse is a much easier situation for the couple, wherein mechanical placement of sperm in the female genital tract at ovulation will often be sufficient to allow conception. HIV, or the therapy for it, may also impact on the efficacy of oral contraceptives. Most experienced practitioners dealing with medically acquired HIV recognize that fertility management forms an important part of the holistic care of people with HIV and their partners.

## PAIN MANAGEMENT AND DRUG INTERACTIONS

Those with a long history of painful bleeding into muscle and joints, sometimes repeatedly over many decades, have often acquired high pain tolerance. Nonetheless, a significant number of hemophilia patients require daily non-steroidal anti-inflammatory drugs to manage chronic arthritis and other orthopedic complications of their past hemarthroses. These agents have their own problems associated with platelet function but are nonetheless often necessary components of the pain management strategy. Opiates may be required for analgesia and supplementing background analgesia for acute injuries can be problematic. Co-existence of liver disease always needs to be kept in mind in people with HIV from transfusion, and the impact of cirrhosis on opiate metabolism is an important consideration. Serum transaminase levels are a poor guide to severity of underlying hepatitis virus-induced liver disease in HIV-infected subjects, so caution with opiate dosages is prudent in all those with a past history of hepatitis C or hepatitis B, whether or not they are currently viremic.

## VACCINATION

HIV-infection impairs vaccine responses to protein and carbohydrate antigens, and generally live vaccines are contraindicated in HIV-infected subjects outside of clinical trials. As the risk of acquiring hepatitis A from blood products is not

trivial in many countries, and as hepatitis A is not inactivated by detergent treatment of coagulation products, non-immune subjects with HIV should be vaccinated with hepatitis A vaccines. For poor responders, such as those with HIV, boosting beyond two doses may be necessary. Should hepatitis B serology not show prior exposure then vaccination with recombinant hepatitis B surface antigen is also recommended. Extended individualized schedules of vaccination and/or higher dose of antigen may be needed to achieve protective levels of antibody to immunogens in HIV positive people of all ages.<sup>43</sup>

## SURGERY

Many of those with medically acquired HIV will require surgery at some stage, for incidental conditions, or those conditions related to their underlying need for blood products or tissues. With modern hematological support major orthopedic surgery, including joint replacement, open heart surgery, vascular surgery and life saving cancer surgery, can all be safely conducted in appropriately experienced centers. Rigorous attention to hemostasis, prevention of nosocomial infection, and care in avoiding unwanted drug interactions, particularly those related to protease inhibitor use and cytochrome P4503A4 inhibition, are all essential components of surgical planning. Some patients are reluctant to have further exposure to blood products, so issues of adequately informed consent must be fully addressed. For all these reasons it is not uncommon for surgery to be delayed, with negative consequences. Experienced multidisciplinary teams have much to offer in the management of surgical patients with HIV, and this applies particularly to those with pre-existing complex medical issues; consequently patient transfer to a tertiary setting is often worth the inconvenience and delay.

## Ongoing Risk Minimization

Strenuous efforts have been mounted worldwide to secure the safety of blood products and develop alternatives to donor-derived materials. Currently, recombinant Factor VIII is increasingly being used for the treatment of hemophilia due to Factor VIII deficiency, providing a level of safety not previously achievable with donor-derived products.<sup>13</sup> Efforts to treat hemophilia by gene therapy offer the prospect of non-infusional treatments in the future, but there are many obstacles to overcome prior to successful gene therapy of a potentially immunogenic protein such as Factor IX.<sup>44</sup> In many countries the cost of recombinant coagulation factors is prohibitive and plasma or plasma fractions such as cryoprecipitate are still in widespread use, with ongoing need to ensure donated product safety. The future safety of donor-derived materials depends on six risk reduction measures, some of which are not suitable for fresh blood and organ protection:

1. Donor selection
2. Laboratory screening by serological and NAT technology
3. Retesting of donors of storeable products at a later date prior to product release

4. Product processing to inactivate viruses
5. Recipient screening and lookback assessment with case finding of infected donors
6. Scrupulous attention to maintaining sterility of equipment used for blood and plasma collection and avoiding iatrogenic donor infection from shared donation collection tubing.

Internationally, however, there remain significant variations in strategies in place in all the above domains, a situation likely to persist for many years to come (Fig. 88.2).

## DONOR SELECTION

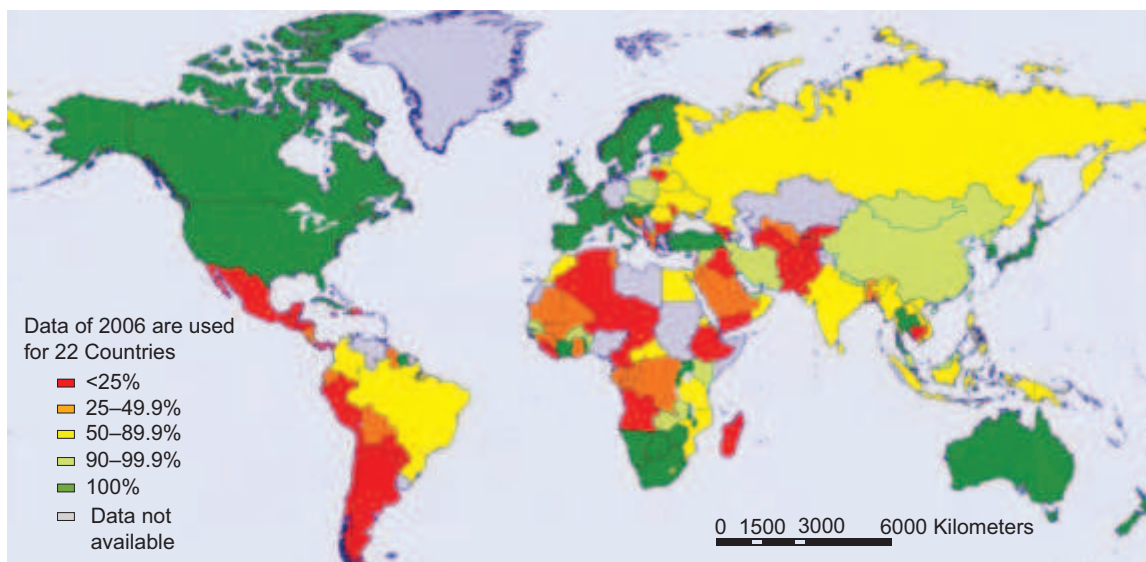

Early attempts to protect the integrity of the blood supply involved rigorous donor selection based on questionnaire responses that included travel and behavior declarations, aimed principally at excluding homosexual male donors. Those potential donors who were perceived on the basis of geographical, medical, or behavioral characteristics to be at high risk of harboring HIV were and continue to be excluded from the donor pool.<sup>45</sup> Detailed interview and risk assessments with surrogate testing for concurrent hepatitis and sexually transmitted infections were carried out in some jurisdictions, stemming from the earlier work on recognition of non-A, non-B hepatitis infections, (subsequently shown to be mainly hepatitis C). These various measures are generally believed to have significantly improved blood safety even prior to HIV serology being available. Recent sophisticated analyses of transfusion-related risk include one study from Brazil where despite use of antibody screening in the region of Santa Catarina, Brazil,<sup>46</sup> the high rates of incident HIV result in calculated risk of blood borne virus (BBV) well above those considered acceptable in most jurisdictions. Undue reliance on serological screening in countries with even higher rates of newly

acquired HIV in heterosexuals continually expands the numbers of transfusion transmitted infections.

For travelers who are returning to low HIV prevalence countries from high-prevalence countries, it is particularly important for their regular practitioner to seek information about any contact with biological products or invasive procedures while away. Travel and medical histories need to be comprehensive and include information about batch numbers if processed products were involved. The international hemovigilance situation is rapidly changing; this reflects changes in true incidence rates, and to an indeterminate degree, the spread of HIV to traditionally low-risk donors such as self-perceived monogamous heterosexuals. The analysis of serology from hemophiliac cohorts from developed countries in the early 1980s cast doubt upon the widely held view that plasma and blood products sourced from volunteer donors was significantly safer than commercially sourced plasma.<sup>6,47</sup> Furthermore, many large contaminated batches of freeze-dried coagulation factors were unwittingly sold world-wide, and few countries escaped some exposure of their hemophilia patients to HIV prior to introduction of heat-treated products, even those with very low background population prevalence of HIV, such as Japan.<sup>48</sup> In recent decades, international cross jurisdiction movement of plasma has further grown and necessitates constant vigilance in donor testing at source. Ensuring integrity of the blood supply at collection has allowed dismantling of some of the barriers to plasma movement across borders.

## SCREENING FOR HIV AND OTHER BBVS BY NAT

Best practice in donor screening is the use of serological screening for HIV-1/2 antibody using high-sensitivity assays with greater than 99% sensitivity for established infection, and a supplementary technique to detect antibody negative viremic subjects, by HIV

**Fig. 88.2:** Percentage of voluntary unpaid blood donation 2007. *Source:* WHO.

antigen detection, or HIV gene sequence detection with NAT methods. However, the reality is that in many jurisdictions hemovigilance for HIV is constrained by the cost implications of enhanced screening, and extends only to antibody screening, even in countries with high prevalence/incidence rates in the general population. That strategy will inevitably result in some transmissions from seroconverting or pre-seroconverting donors unaware, (or in denial), of their risk. The 2008, United Nations General Assembly Special Session indicators of progress in the battle against HIV include indicator number 3, the percentage of donated units screened in a quality assured manner.<sup>49</sup> Setting indicators such as these allows a scorecard approach to the assessment of progress in achieving enhanced blood safety. On the other hand, commercial plasma fractionation is a large industry and a significant proportion of plasma collections still derive from paid plasma donors.

### RETESTING OF DONORS

For donors of plasma, it is possible to quarantine the product until the donor has been retested at a later stage. Similar strategies have been used for semen donors in *in vitro* fertilization programs and for tissue banking. In most blood banks handling blood products of short shelf-life, logistic considerations prevent the widespread use of a donor retest strategy, except for regular donors in plasmapheresis or cell apheresis programs.

### INACTIVATION OF VIRUSES

Although prolonged heat treatment can inactivate HIV, neither freezing nor lyophilization impacts significantly on the viability of HIV in contaminated blood products. Heat treatment inactivation and/or solvent-detergent exposure during manufacture for lyophilized coagulation factors was introduced in a piecemeal fashion<sup>48</sup> across blood banking jurisdictions during the early and mid 1980s. The Scottish National Blood Transfusion Service was the first to develop a means of treating lyophilized coagulation products at 68°C in 1984, and made the technology available to other blood banks and plasma fractionators, enabling Australia to be the second jurisdiction with heated licensed products in May 1985. Thereafter, heated lyophilized products or solvent/detergent treated products were widely used by the end of 1985, and almost universally used in developed countries by early 1986, marking a time after which lyophilized heat treated or solvent/detergent treated coagulation factors ceased to be a risk for HIV transmission. Subsequently a variety of chemical and physical viral inactivation processes,<sup>50</sup> despite their lack of efficacy against all potential BBVs, have become the standard approach to enhancing safety of manufactured coagulation factors, supplemented in many cases by additional heating. Most licensed solvent/detergent processes rely on tri (n-butyl) phosphate (TNBP) as the solvent moiety, and a variety of detergents are the other component of the processes, most of which are proprietary.

### POST-RELEASE RECIPIENT SCREENING

Confidence in the safety of the currently available blood products has led to the view that routine post transfusion screening for newly acquired BBVs is not warranted in the absence of an index case of transfusion related viral infection or the identification of an infected donor from screening. Nonetheless, many centers continue to test frequently infused and transfused recipients for BBVs, with a low yield of positive diagnoses, and the generation of considerable anxiety on the part of recipients.

### MAINTAINING STERILITY OF EQUIPMENT USED IN BLOOD AND PLASMA COLLECTION

Many reports during the 1980s and into the 1990s pointed to increased rates of chronic viral infection in paid donors in plasmapheresis programs.<sup>51</sup> While some countries have attributed this to the plasmapheresis program serving as a source of income for intravenous drug users, some outbreaks, such as one in Mexico, were clearly the consequence of iatrogenic transmission of viruses to donors during plasmapheresis.<sup>52</sup> International standards call for single-use equipment, sterile swabs, and wherever feasible, non-reuseable bedside equipment, as the means of minimizing the potential for donors themselves to become infected during donation, the consequence of which is contamination of future donations.

### Cost-Benefit Considerations

At present, in low HIV-prevalence countries, enhanced hemovigilance with individual sample NAT testing superimposed on single sample serology, has a high cost-to-benefit ratio but the community rightly has expectations that the blood supply is as safe as humanly possible, thereby justifying the costs involved.<sup>53,54</sup> Most high-income countries have moved to high-throughput high speed NAT of all donated samples over the last decade, and other enhanced hemovigilance steps as outlined above. In such countries these protocols of donor selection and testing should make newly acquired HIV and other viruses from blood transfusion or blood products extremely uncommon in the future.

### Other Future Issues

Other future issues for transfusion recipients with HIV are numerous. Significant numbers of infants were infected in the early 1980s and many of these, now adults, have HIV-negative heterosexual partners, and are currently seeking to have children. Assisted reproduction services are not widely available to assist such couples and those caring for them require local knowledge of available services and knowledge of legal and financing regulations that are pertinent. At the other end of the age spectrum, long-term

survivors of the wave of HIV infection of the early 1980s include a subgroup in which ageing with its attendant co-morbidities provides additional management complexities. Complications of previous intracerebral bleeding can complicate interpretation of neurocognitive decline of age and false diagnosis of HIV related neurocognitive decline is an ever-present diagnostic hazard to the clinician.

The human stories behind the statistics of transfusional HIV have much to teach the student of public health. Moralistic thinking clouded scientific debate in the early years of the AIDS epidemic, and discrimination abounded in most, if not all countries. People living with HIV acquired from medical interventions have often lived through periods of extreme hardship, fear, and physical illness all attributable to the HIV virus. Laws, charitable institutions, and healthcare funding models needed to adapt to the reality of HIV and it was often in the context of dealing with the needs of transfusion cases that discriminatory practices were overturned. The survivors still bear the scars of the time prior to the recognition of their plight and many still harbor a fear of the “next virus,” a fear that is in no way irrational as the waves of other blood borne infections have been confronted. Hemophiliacs worldwide have needed to be vaccinated against hepatitis A because of its resistance to detergent and heat; they have been assessed for prion-related disease and have been aware of the threats of west Nile virus and parvovirus in the US and Europe, and of other microbes so far undiscovered. The lessons of the need for hemovigilance have been learnt at all levels of healthcare but most poignantly by those who have cared for those infected by transfusional HIV and the other BBVs.

Courts have varied in their judgment of the extent to which those managing the blood supply and its downstream processing have been misled, negligent or worse.<sup>55</sup> Healthcare workers are constantly reminded of the need to treat blood products as potentially contaminated, and harboring any number of threats to the recipient. At the present time, as a result of the efforts to secure the blood supply, the risk of an adverse outcome from blood transfusion is far greater from misidentification, transfusion incompatibilities, and bacterial infection, than it is from infection with BBVs. Efforts need to continue, both at a regulatory level<sup>56</sup> and in basic science laboratories, to further lower those risks which are still very high in many low income countries,<sup>57</sup> and to maximize the health of those who have already been infected.

Just as the last two decades delivered huge advances stemming from molecular biology, in particular, widespread availability of recombinant coagulation factors such as Factor VIII thereby eliminating reliance on donor-derived Factor VIII, it is conceivable that the next decade will provide advances in gene therapy such that people who have acquired their HIV infection from infused blood are protected by cells armed by gene therapy to resist HIV.<sup>58</sup> Finally, the need for many forms

of donor blood product exposure may be reduced by somatic cell gene therapy which is particularly suitable for treatment of congenital coagulation disorders.<sup>59</sup>

### Summary

In the half-decade preceding the discovery in 1983 that acquired immune deficiency syndrome (AIDS) was caused by a blood-borne retrovirus, which was also readily transmitted sexually, HIV was frequently an unsuspected contaminant of donated blood and manufactured therapeutic products of human origin. Infected recipients began developing AIDS as early as 1982 in the US, and soon afterwards cases were recognized in many other countries. Despite the high mortality of HIV disease in the time prior to the use of effective combination antiretroviral therapy (cART) in the mid 1990s, many people infected with HIV by blood products nonetheless survived the many intervening years. In many countries, long-term HIV infected blood product recipients now are predominant among living medically acquired HIV cases and number many tens of thousands worldwide.

Most countries have introduced sophisticated screening tests of blood and tissues as part of enhanced hemovigilance for transmissible viruses; however, even in those with implementation of viral nucleic acid testing (NAT) of donations occasional new HIV infections still occur in recipients. Newly acquired transfusion and tissue transplant related HIV infections are generally the consequence of the limited sensitivity of HIV antibody tests in detecting the infection within the first few weeks after exposure, as well as the limited success in preventing high-risk donors from donating.

The principles of management of medically acquired HIV are in most respects similar to those applicable to sexually acquired infection, as both modes of acquisition have very similar prognosis and respond to antivirals comparably. The complexity of management is, however, increased by the common presence of pre-existing co-morbidities and transfusion-acquired co-infection with chronic hepatitis viruses. Medical conditions such as hemarthroses, muscle damage, and cerebral injury from prior bleeding episodes further complicate management in hemophiliacs. Enthusiasm for the use of the most recently available antiretroviral agents is tempered in those with hematological diseases by concerns about the potential for adverse effects on coagulation and homeostasis. Integrase inhibitors and cellular CCR5 co-receptors binders are yet to have their long-term safety fully determined in coagulopathy patients, in others requiring frequent blood products, and in those with co-existing chronic hepatitis. Thus there is a need for ongoing evaluation of the safety of new antivirals in subjects with hemophilia and hemoglobinopathies, during the early and later phases of drug development, and in post-marketing monitoring. Ultimately, the lifespan of people with medically acquired HIV living in the post cART era is likely to be determined principally by the outcome of co-morbid conditions, co-infections with chronic hepatitis viruses, and the course of the underlying disease that originally prompted transfusion of blood.

- HIV infection from contaminated donor blood exposure may still occur despite screening.
- Most donor-derived blood cell-free products undergo viral inactivation steps in manufacture to minimize the risk of viral transmission.
- Implementation of quality assured standards for virus testing in global blood banking is a high priority.
- Hepatitis virus co-infection with hepatitis C, hepatitis B or both may impact on decisions in timing of initiation of therapy for HIV and the choice of agents in cART
- Co-morbidities in hemophiliacs patients warrant consideration in planning HIV therapy.

## HIV in Injection and Other Drug Users

Jaimie P. Meyer • Frederick L. Altice

### Introduction

Injection drug use (IDU) and HIV are pervasive overlapping epidemics<sup>1-3</sup> with a vast array of social and health consequences at both the individual and societal levels. IDU is particularly important in the HIV epidemic, not only as a vehicle of viral transmission among IDUs but also serves as a bridge from IDUs to their sexual partners and to others within broader social networks.<sup>4</sup> For the clinician, it is imperative to recognize drug use in HIV-infected patients to effectively screen and vaccinate for concurrent related infections, monitor for end-organ complications, and offer treatment for substance abuse, HIV, and other co-morbid conditions. Of particular importance to the HIV clinician are the special clinical features of HIV disease in drug-dependent patients, the treatment of HIV disease in this population, the special challenges in providing care to drug users, and the treatment of drug dependence itself. Engaging HIV-infected injection drug users (HIDUs) in care and initiating antiretroviral therapy (ART) is of the utmost importance. ART, when prescribed and adherence is optimized, improves health outcomes for HIV and many of its co-morbid conditions, including tuberculosis, viral hepatitis, and renal and cardiovascular disease.<sup>2</sup> On a public health level, addressing drug use in people living with HIV/AIDS (PLWHA) is critical for secondary HIV, hepatitis C, and tuberculosis prevention efforts. This chapter offers a broad perspective on concurrent HIV infection and injection drug use, including an overview of substance abuse and evidence-based treatment options, other common co-morbidities in this population, and public health strategies to address these issues.

### Healthcare Disparities for HIV-Infected Drug Users

Highly active antiretroviral therapy (HAART) has greatly benefitted PLWHA, including decreased morbidity, mortality,<sup>5</sup> emergency department use,<sup>6</sup> and hospitalization,<sup>7</sup> and has been demonstrated to be cost-effective<sup>8</sup> and improves quality of life.<sup>9</sup> Despite the widespread availability of antiretroviral medications

in resource-rich settings, IDUs have derived less benefit than other populations.<sup>2,10,11</sup> The reasons for inequality are multifactorial and include differences in access to and prescription of HAART. In low- and middle-income countries, HIDUs are less likely to receive ART than PLWHA who do not use drugs.<sup>12</sup> Even in industrialized countries, HAART is often withheld from IDUs, amounting to significant violations of basic human rights.<sup>13</sup> Potential barriers to HIV and substance abuse treatment include social marginalization, fear of criminal sanctions, costs, and incarceration.<sup>12</sup>

Drug-dependent people living with HIV experience ongoing discrimination. In many societies worldwide, both HIV and illicit drug use are stigmatized such that either or both conditions are often cloaked in secrecy and may result in a lack of detection and treatment.<sup>14,15</sup> In some cultures, ongoing substance use is perceived as a self-inflicted disease resulting from personal moral failures.<sup>16</sup> Drug users are seen as having little social worth. Physicians may view drug users as manipulative, unmotivated, and undeserving of care,<sup>17</sup> in part because many HIV providers are poorly educated about drug dependence. In turn, many drug users are mistrustful of the healthcare system and harbor expectations that they will be treated punitively.<sup>18-20</sup> As a result of these prevailing misconceptions, HIDUs are often hidden by circumstances and/or choice from mainstream medical care.

Providing clinical care for drug users with HIV is often challenging and stressful for clinicians and other healthcare workers because of the complex array of related medical, psychological, and social problems. Frequent underlying and untreated psychiatric disease, including personality disorders, often contribute to these difficulties. Substance misusers may also have increased difficulties with adherence to medications<sup>21-24</sup> which may be compounded by their underlying co-morbid diseases, increased side effects, and drug interactions. The idea that all drug users are non-compliant with HAART and thus risk development of drug resistance is a common misperception among healthcare providers. This myth has been discredited by scientific evidence.<sup>16</sup> Best predictors of HAART adherence in one recent meta-analysis of HIDUs were receiving opioid

substitution therapy and/or psychosocial support.<sup>25</sup> Treatment failures are more often the result of system-wide structural barriers to care.<sup>13</sup> Even when available, healthcare services are often constructed in ways that are difficult for many drug users to access. They are either absent from communities with high prevalence of drug use or do not accommodate the chaotic and sometimes unpredictable use of services characteristic of drug-using populations. Indeed, systems of integrated care for HIV-infected drug users are lacking.

## Overview and Management of Substance Use Disorders in People with HIV

A list of commonly used illicit drugs along with evidence-based treatments is presented in Table 89.1 and will be described in more detail in this section. For further information, please refer to the National Institute on Drug Abuse website ([www.drugabuse.gov/drugpages](http://www.drugabuse.gov/drugpages)) and that of the World Health Organization (WHO) ([www.who.int/substance\\_abuse](http://www.who.int/substance_abuse)).

**Table 89.1:** Common Legal and Illegal Drugs Consumed and Their Impact on HIV

Substances used	Common adverse clinical consequences of ingestion	Mode(s) of use	Impact on HIV	Evidence-based medication-assisted treatment(s)
Opioids (heroin, morphine, hydromorphone, codeine, poppy-straw)	Respiratory depression, coma, overdose; physical and psychological dependence	Injection; inhalation (smoked or sniffed), oral (synthetic only)	↓s access to and utilization of care; ↓d prescription of ART, ↓ adherence to ART	Methadone (oral); buprenorphine (sublingual); naltrexone (oral, injectable)
Cocaine (white powder, crack)	Agitation, hyperthermia, tachycardia, arrhythmia, hypertension, convulsions, cardiac and CNS disturbances, hallucinations, death, psychological dependence.	Injection; inhalation (smoked or sniffed)	↓s access to and utilization of care; ↓d prescription of ART; ↓d adherence to ART; ↑d sexual and drug risk behaviors	None
Benzodiazepines	CNS depression, sedation, ataxia, amnesia and coma; deaths are rare when benzodiazepines are taken alone; physical and psychological dependence are rapid and profound.	Injection; oral	Associated with ↑d sexual and drug risk behaviors; ↓d adherence to ART; ↑d sexually transmitted infections	Slow supervised taper and withdrawal required
<b>Club Drugs</b>				
Methamphetamine and amphetamine-group substances (AGS)		Injection; inhalation; per rectum	↓s access to and utilization of care; ↓d prescription of ART, ↓d adherence to ART; some ART ↑s risk of AGS overdose	None
3,4 methylenedioxy-methamphetamine (MDMA)	With overdose, serotonin syndrome, stimulant psychosis, and/or hypertensive crisis, cognitive and memory impairment, acute delirium, cardiac arrhythmias or infarction, coma; profound depression several days after use	Oral (tablet)	↓d adherence to ART on days of MDMA use	None
Ketamine	Hypertension, cardiac arrhythmias, cognitive impairment;	Injection, inhalation (sniffed or smoked)	Not known	None
Gamma hydroxybutyrate (GHB)	Oversedation, coma, death, seizures, hypotension and shock, psychosis and agitation.	Oral (liquid)	Not known, but likely similar to alcohol	None
Nitrates/nitrites (poppers)	Methemoglobinemia, hemolytic anemia especially those with G6PD deficiency, hypotension, cardiac arrhythmias	Inhalation (liquid)	Associated with ↑d HIV risk behaviors	None
Alcohol	CNS sedation, some malignancies, hepatic injury, dietary deficiencies, pancreatitis, gastritis, neuro-cognitive deficits	Oral	↑s hepatotoxicity; ↑s peripheral neuropathy; ↓s access to and utilization of care, ↓d prescription of ART, ↓d adherence to ART	Naltrexone (oral, depot injection); acamprosate; disulfiram

Reproduced with permission from Lancet, Altice 2010.<sup>2</sup>

↓/↑s, decreases/increases; ↓/↑d, decreased/increased.

The drugs most closely associated with HIV infection globally are heroin and cocaine, but amphetamine-group substance (AGS) use is an evolving problem.<sup>26</sup> Injection with shared contaminated needles, syringes, drug preparations, or other injection paraphernalia carry the greatest risk for HIV and other blood-borne infections transmission.<sup>27,28</sup> To transform substances from solid to liquid form suitable for injecting, one first heats the solid drug in a cooker or spoon. After it cools, the liquid is drawn up in a syringe through cotton to grossly filter out other debris. A needle is then attached and the drug is injected either intravenously (most commonly in the brachiocephalic veins of the antecubital fossa) or subcutaneously in a process known as “skin popping.” Often, unsterile injecting techniques are used. Injection paraphernalia may be shared and residual blood may be present in the equipment itself. As such, the processes of preparing and injecting drugs provide ample opportunities for microbial cross-contamination and viral transmission.

Non-injection drug use may also contribute to adverse outcomes in HIV-infected patients. Use of non-injection stimulants, such as cocaine and methamphetamine, is associated with increased HIV risk behaviors<sup>29,30</sup> and suboptimal adherence to HIV treatment.<sup>31</sup> Non-injection drugs also influence cellular immune responses and may interact with ART, potentially leading to increased incidence or severity of adverse events.<sup>32</sup> Non-injection drug and alcohol use increasingly facilitates HIV transmission, particularly among women, through its association with the exchange of sex for money or drugs.<sup>33</sup> Furthermore, the disinhibition that occurs with drug and alcohol intoxication is closely linked with risk-taking activities (including unprotected sex and needle-sharing), increasing the likelihood of HIV exposure and transmission.<sup>34</sup>

## COMMON DRUGS OF ABUSE

### Heroin

Heroin, the most widely used opioid, is a short-acting, semi-synthetic opiate produced from opium. It may be smoked, inhaled, or injected; peak heroin euphoria begins shortly after injection and lasts approximately 1 hour, followed by 1–4 hours of sedation. Withdrawal symptoms commence several hours later. As a consequence, most heroin-dependent individuals inject 2–4 times per day. Many heroin users will mediate the sedating effects of heroin by injecting a small amount of cocaine with heroin, a mixture known as a “speedball.” Unsterile methods of injection, unpredictable concentrations in street-derived samples, acute euphoria resulting in increased risk-taking, adulterants in the injection mixture, and the lifestyle necessary to procure drugs are responsible for the bulk of heroin-associated medical complications.<sup>35</sup>

### Cocaine

Among the stimulants, cocaine is most commonly used. Cocaine is available as a water-soluble hydrochloride salt that is either injected or taken by nasal inhalation (“snorted”). Although cocaine hydrochloride is destroyed by heat, it may be chemically converted to a free-base

(“crack”) cocaine, which can be smoked. Pulmonary absorption of “crack” is as rapid as intravenous injection of cocaine. Cocaine’s half-life is short, resulting in the need for frequent administration. Active cocaine users may inject or inhale cocaine as many as 20 times a day. Cocaine induces feelings of elation, omnipotence, and invincibility and invokes rapid development of psychological dependence. The most severe direct medical consequence of cocaine use is vasospasm, an idiosyncratic response that can result in myocardial infarction and cerebrovascular accidents in young persons without any evidence of vascular disease.<sup>35</sup>

### Benzodiazepines

Benzodiazepines, a class of sedative hypnotics, are sometimes injected after crushing the tablet formulation, often resulting in soft-tissue and vascular complications.<sup>36</sup> When combined with other drugs, benzodiazepine use is associated with decreased retention in drug treatment, increased HIV risk behaviors, fatal and non-fatal overdose, and increased mortality.<sup>37–39</sup> Like opioids, benzodiazepines cause both physical and psychological dependence and can result in dangerous complications associated with withdrawal.<sup>40</sup>

### Amphetamines

AGS are psychostimulants that include amphetamine, methamphetamine, and their derivatives.<sup>26</sup> AGS can be smoked, snorted, injected, or administered rectally. Like cocaine, ingestion produces stimulation and similar feelings of euphoria; AGS, however, have a longer duration of action than cocaine, with a half-life of 9–12 hours. Psychological dependence develops rapidly, as does tolerance, and escalation of dose and frequency is required. Because of this pharmacokinetic profile, AGS are often used in a sexual context to facilitate disinhibition and thus have been linked to high-risk sexual behavior and HIV transmission, especially among men who have sex with men.<sup>26,41</sup> For healthcare providers, recognition of AGS abuse in HIV-infected patients is critical. AGS and some antiretrovirals, including ritonavir and delavirdine, share a common metabolic pathway and co-administration has been linked to amphetamine overdose fatalities in several published case reports.<sup>30</sup>

### Alcohol

Alcohol use disorders (AUDs) are common among PLWHA, with an estimated prevalence of 8–41%,<sup>42–45</sup> In fact, AUDs are 2–4 times more common among PLWHA than among their uninfected peers.<sup>46</sup> Patterns of hazardous alcohol consumption are most prevalent in global regions with concentrated HIV epidemics, particularly in eastern and southern Africa.<sup>47</sup> Heavy alcohol use negatively acts synergistically with HIV in several ways, including increased HIV risk-taking behaviors<sup>48–50</sup> and thereby increased risk for transmission to others,<sup>51</sup> decreased retention in care,<sup>52</sup> poor adherence to ART,<sup>53,54</sup> decreased likelihood of HIV virologic suppression,<sup>11,55</sup> acceleration of cognitive decline,<sup>56</sup> acceleration of hepatic fibrosis in the setting of HCV co-infection,<sup>57</sup> and overall increased mortality.<sup>42,58</sup>

## MANAGEMENT OPTIONS FOR SUBSTANCE ABUSE

The World Health Organization (WHO) defines substance dependence as the psychological and/or biological need for alcohol or drugs in order to function or survive, a pattern that emerges only after repeated use. Substance abuse is defined as a maladaptive pattern of use that persists in spite of negative social, psychological, or physical consequences.<sup>59</sup> Together, abuse and dependence are grouped under a larger umbrella of substance use disorders (SUDs). A wide range of treatment options for SUDs exist and are best used in an integrated way that is tailored to the individual.

## Evidence-Based Medication Assisted Therapies

Medication-assisted therapies (MATs) use clinician-prescribed medication to reduce the negative consequences of drug use. MAT alone, or when coupled with brief counseling/education, can

result in impressive outcomes, improving the psychological and physiological disruptions that perpetuate the often unstable life of a drug-dependent person.<sup>60</sup> Available MATs for opioid and AUDs are listed in Table 89.2. There are no currently available evidence-based pharmacotherapies for cocaine or amphetamine abuse; counseling remains the only evidence-based treatment modality shown to decrease use of cocaine and methamphetamine.<sup>61,62</sup>

### MATs for Opioid Use Disorders

Medically supervised opiate withdrawal followed by intensive outpatient treatment may be a viable treatment option for users with relatively low addiction severity. These include short-term opiate users (less than 2 years), young adults, and non-injectors.<sup>63,64</sup> The withdrawal process involves a supervised gradual taper from opioids using methadone or buprenorphine.<sup>65</sup> Alternatively, medically supervised withdrawal may involve

**Table 89.2:** Available Medication-Assisted Treatments for Opioid and Alcohol Dependence

Medication	Type of dependence	Mechanism of action	Pharmacological properties	Adverse side effects	Substance abuse treatment outcomes	Impact on HIV	Other issues
Methadone (MET)	Opioid	Pure opioid $\mu$ -receptor agonist	Half-life 24–36 hrs. Ingested orally as tablet or liquid. Achieves steady state within 5 days	Tolerance to side effects usually develops; diaphoresis, constipation, and amenorrhea (menses usually return after 12–18 mo). Excessive dosing or when combined with alcohol may cause overdoses or death.	↓ relapse to illicit opioid use; ↓ number of days using illicit opioids; ↓ opioid and cocaine use after release from prison; ↓ criminal activity; ↑ employment; cost-effective	↓ injection and HIV transmission; ↑ retention in HIV care; effective supporter of directly administered ART (DAART); ↑ effectiveness of ART	No euphoria felt after being on stable methadone dose; doses of 30–60 mg daily will block opioid withdrawal symptoms, but this dosage seldom produces abstinence. Instead, higher doses in the 80–120 mg daily range are needed to ↓ opioid craving and ↓ illicit drug use. These higher doses are also associated with greater retention in treatment. Only administered in highly structured treatment settings with directly observed therapy.
Buprenorphine (BPN)	Opioid	Partial opioid $\mu$ -receptor agonist and partial $\kappa$ -receptor antagonist	Half-life 24–36 hrs. Administered sublingually. Slow dissociation from the $\mu$ -receptor allowing alternate-day dosing	Improved safety profile compared to methadone; unlikely to cause overdose or respiratory depression; higher binding affinity for the $\mu$ -receptor than heroin or methadone, therefore precipitates withdrawal in person still with opioids in their system.	↓ relapse to illicit opioid use; ↓ number of days using illicit opioids; ↓ opioid and cocaine use after release from prison; ↓ criminal activity; ↑ employment; cost-effective	↓ injection and HIV transmission; ↑ retention in HIV care; effective supporter of DAART; ↑ effectiveness of ART; ↑ retention on ART after release from prison	↓ likelihood for medication diversion and abuse potential compared to methadone; injection of BPN in opioid dependent persons precipitates withdrawal symptoms; may be given in less structured settings, including as part of integrated HIV care
Buprenorphine/naloxone	Opioid	Partial opioid $\mu$ -receptor agonist and partial $\kappa$ -receptor antagonist; naloxone is a short-acting $\mu$ -receptor but not orally bioavailable antagonist	Half-life 24–36 hrs. Administered sublingually. Slow dissociation from the $\mu$ -receptor allowing alternate-day dosing	Same as for buprenorphine; naloxone used to reduce likelihood for diversion and injection	Compared to high dose methadone, retention in treatment is lower	Same as for buprenorphine; when injected, likely results in more frequent injecting and increased risk for HIV transmission	Used to ↓ likelihood of illicit injection because coformulation with naloxone precipitates withdrawal symptoms in opioid dependent patients when used parenterally; injection frequency, however, may ↑ the frequency of injections

Medication	Type of dependence	Mechanism of action	Pharmacological properties	Adverse side effects	Substance abuse treatment outcomes	Impact on HIV	Other issues
Naltrexone	Opioid	Pure $\mu$ -receptor opioid antagonist.	Oral formulation dosing is daily or alternate-day dosing; Injectable formulation administered intramuscularly monthly (improves adherence)	Hepatotoxicity possible; has been administered safely in HCV-infected patients	Retention in treatment is lower than for MET or BPN, but may be considered in highly motivated patients.		Discourages opioid use by diminishing the pleasurable effect of and craving for opioids, and has demonstrated efficacy in highly motivated populations
Naltrexone	Alcohol	Blocks the pleasant and reinforcing effects of alcohol by preventing the stimulation of opioid receptors and the reduction of dopamine release in the ventral tegmental area (VTA)	Oral formulation dosing is daily or alternate-day dosing; Injectable formulation administered intramuscularly monthly (improves adherence)	Hepatotoxicity possible; has been administered safely in HCV-infected patients	Superior to behavioral counseling and acamprosate for treatment of AUDs in HIV uninfected persons. $\uparrow$ s time to relapse, $\downarrow$ s number of heavy drinking days	Not studied in HIV-infected subjects	
Acamprosate	Alcohol	Structural analog of the GABA neurotransmitter; normalizes glutamatergic neurotransmission; slow acting, may attenuate relapse in some	Orally dosed with two tablets three times per day; adherence may be problematic	Few adverse side effects	$\uparrow$ d abstinence confirmed in placebo-controlled trials, but no benefit in preventing relapse by itself or in combination with counseling.	Not studied in HIV-infected subjects	Less effective than naltrexone, equivalent to counseling, and superior to placebo for alcohol relapse prevention; approved by US FDA (2004) for relapse prevention in subjects who have already withdrawn from drinking
Disulfiram	Alcohol	Inhibits acetaldehyde dehydrogenase and causes accumulation of acetaldehyde when alcohol is consumed. This leads to painful symptoms such as facial flushing, dyspnea, nausea, vomiting, and headache, thereby discouraging relapse to alcohol consumption.	Orally dosed, half-life 24 hrs;	Nausea and vomiting if alcohol is ingested; hepatotoxicity	Not studied in HIV-infected subjects; should not be combined with Amprenavir (probable interaction) or Metronidazole (probable interaction)	Hepatotoxicity; Causes profound nausea and vomiting when alcohol is ingested	May be useful when combined with other interventions, including methadone when a patient is opioid-dependent

Reproduced with permission from Lancet, Altice 2010.<sup>2</sup>

$\downarrow/\uparrow$ s, decreases/increases;  $\downarrow/\uparrow$ d, decreased/increased.

abrupt discontinuation of opioids with management as needed of withdrawal symptoms. Although more symptomatically uncomfortable for patients and with demonstrated inferior outcomes, clonidine may be used to alleviate some symptoms of opioid withdrawal.<sup>65</sup>

Relapse to drug use among chronic opiate users exceeds 85% when patients undergo supervised opiate withdrawal without chronic opiate substitution therapy.<sup>66</sup> MAT with opiate substitution therapy is the most effective treatment for opioid dependence (OD).<sup>67,68</sup> Currently, several MAT options exist: methadone, buprenorphine, and naltrexone and are described in further detail in Table 89.2. Methadone and buprenorphine are the most effective MATs for treating

OD,<sup>69</sup> though naltrexone has achieved some success in highly motivated patients.<sup>70</sup> This is particularly true using the extended-release formulations.<sup>71</sup>

### MATs for Alcohol Use Disorders

Though pharmacotherapy for treating AUDs has been found to be superior to behavioral interventions, its use in PLWHAs has not been systematically evaluated.<sup>58,63,70,72–76</sup> There are currently three FDA-approved medications for managing AUDs: naltrexone, acamprosate, and disulfiram which are described further in Table 89.2. Naltrexone is the most effective treatment thus far for relapse prevention and treatment of AUDs.<sup>70,72</sup>

MAT, when appropriately dosed, is particularly important for HIDUs because it enhances access and adherence to ART and HIV treatment, improves retention in HIV care and decreases HIV risk-taking behaviors. As the number of HIDUs enrolled in MAT expand, so too must the knowledge of drug interactions that occur among MAT, ART and other medications to treat co-morbid conditions.<sup>60,77</sup> Details on these important pharmacologic interactions have been described previously.<sup>2,77</sup>

## Overview of Co-morbid Medical Conditions

Although the natural history of HIV disease among drug users is similar to that in other transmission risk categories, drug users are at increased risk for a number of other infections, including tuberculosis, bacterial pneumonia, skin and soft tissue infections, and endovascular complications.<sup>78</sup> Multiple features of injection drug use contribute to the increased risk of infection in this population.

These include:

- (i) Unsterile injection techniques
- (ii) Contamination of injection equipment or drugs with microorganisms, which may be present in residual blood in shared injection equipment
- (iii) Increased rates of skin, mucous membrane, and nasopharyngeal carriage of pathogenic organisms (including resistant organisms like methicillin-resistant *Staphylococcus aureus*)
- (iv) Poor dental hygiene
- (v) Impairment of gag and cough reflexes resulting in increased risk for aspiration and pneumonia
- (vi) Humoral and cell-mediated immunity deficits and phagocyte-mobility and killing defects induced by HIV infection and/or drug use
- (vii) Increased prevalence of exposure to certain pathogens (notably *Mycobacterium tuberculosis*)
- (viii) Alteration of the normal microbial flora by self-administered antibiotic use
- (ix) Concomitant behaviors such as cigarette smoking, alcohol use, or exchange of sex for drugs or money that increase risk of associated infections
- (x) Decreased access to and/or lack of appropriate use of preventive and primary healthcare services.

Recognition of co-morbid infections in HIDUs is critical to preventing significant medical complications and death but may be challenging because infections may present atypically in the setting of HIV-associated immunosuppression. Although most of these infections and other complications were common among drug users prior to the HIV epidemic, HIV has accentuated their incidence, severity, and clinical presentation.<sup>79,80</sup> In both inpatient and outpatient settings, these infections are often more common than specific HIV-related complications and often confound both diagnosis and treatment.<sup>35</sup> Table 89.3 summarizes the various infectious complications found in HIDUs by organ system.

**Table 89.3:** A Summary of Complications Related to Drug Use Among HIV-infected Injection Drug Users (Adapted from Bruce 2007)<sup>35</sup>

Location	Disease	Organism(s) or etiology	Treatment	Comments
Skin and soft tissue	Cellulitis	Group A and other streptococci, <i>Staphylococcus aureus</i>	Anti-staphylococcal and anti-streptococcal agents	Consider hospitalization; Consider MRSA depending on local epidemiology
	Abscess	Same as for cellulitis	Same as for cellulitis	Incision and drainage
	Necrotizing fasciitis	Polymicrobial, clostridial infections	Parenteral antibiotics to cover both Gram (+) and (-) organisms	Consider if crepitus noted; immediate surgical consultation required
	Septic thrombophlebitis	<i>Staphylococcus aureus</i>	Anti-staphylococcal agents	Surgical exploration and vein ligation
Cardio-vascular	Endocarditis	<i>Staphylococcus aureus</i> , streptococci, enteric Gram (-) rods	Anti-staphylococcal agents until cultures grow; Treat for 4–6 weeks;	Consider diagnosis of endocarditis if: (a) Regurgitant murmur; (b) Presence of peripheral or pulmonary emboli; (c) Blood culture (+); (d) Evidence of vegetation on echocardiogram
	Myocardial infarction (MI)	Substance induced – associated with vascular spasm and cocaine and AGS use; ↑d pro-inflammatory response from HIV and HCV; potential small ↑s from PI-based regimens	Fibrinolytics and supportive care; lipid-lowering agents among those with hyperlipidemia and smoking cessation	Drug-induced MI associated with no evidence of endovascular stenosis on angiography
Pulmonary	Community-acquired pneumonia	<i>Streptococcus pneumoniae</i> , <i>Haemophilus influenzae</i> , atypical organisms	PCN, cephalosporin, macrolide or tetracyclines	Treatment is typically empiric, based upon local epidemiology
		<i>Pneumocystis jiroveci</i>	TMP/SMZ, TMP/dapsone, atovaquone, pentamidine, primaquine/clindamycin	Most common when CD4 < 200 or CD4% < 14%; Consider even with normal chest X-ray

Location	Disease	Organism(s) or etiology	Treatment	Comments
		<i>Mycobacterium tuberculosis</i>	Isoniazid Rifampin Pryzinamide Ethambutol	Consider rifabutin due to PI interactions; Rifampin markedly decreases methadone and buprenorphine levels; start ART as soon as possible
		Atypical mycobacteria ( <i>M. kansasii</i> , <i>M. fortuitum</i> , <i>M. xenopi</i> , etc.)	Antimicrobials dependent on specific organism	
		Influenza A	Oseltamivir, zanamivir, amantadine, rimantadine	Influenza symptoms prolonged and influenza-related complications higher in HIV +; Influenza vaccination recommended annually
		H1N1	Oseltamivir, zanamivir	ART and increased CD4 associated with decreased hospitalization and mortality; H1N1 influenza vaccination recommended
	Septic emboli	<i>Staphylococcus aureus</i> , streptococci, enteric gram (-) rods	Anti-staphylococcal agents until cultures grow	Common complication in HIDUs, consider with pleuritic chest pain; treatment similar to endocarditis
Liver	Hepatitis	Hepatitis B virus	ART should be used in all co-infected patients and should include tenofovir + lamivudine or emtricitabine; Interferon occasionally for certain HBV genotypes; Entecavir and telbivudine used only if on fully suppressive ART regimen	Defined as being HBsAg positive; if HBV is to be treated, ART regimen should be used. Exclude hepatitis delta superinfection in all HBsAg + subjects.
		Hepatitis C virus	Pegylated Interferon + weight-based Ribavirin	Defined as being HCV antibody positive with detectable RNA
Nervous system	Altered mental status	Substance-induced psychosis	Observation and removal of the inciting agent	Includes opioids, cocaine, AGS, phencyclidine, psilocybin, ketamine, MDMA, others
		Brain abscess and embolism	Same as for endocarditis	CNS imaging (CT or MRI) used to monitor response to therapy
		Toxoplasma encephalitis	TMP/sulfadiazine or TMP/clindamycin	85–95% have positive anti-toxoplasma antibody; presentation typically with focal findings (e.g., seizure, altered mental status, CVA, etc.); CNS imaging (CT or MRI) used to diagnose and monitor response to therapy
		Tuberculosis meningitis or encephalitis	Same as for TB except INH dose ↑d to 600 mg per day	ART may be started cautiously, but may need serial lumbar punctures to ↓ intracranial pressure associated with immune reconstitution
		Cryptococcal meningitis	Amphotericin B induction followed by fluconazole maintenance	ART should be initiated as soon as possible (see TB meningitis)
		Dementia	ART is recommended	May be exacerbated by chronic drug use; Must rule out all other causes; diagnosis of exclusion
		Head trauma	May cause neurocognitive impairment and/or seizures	
	Neuropathy	HIV and HCV	Treatment aimed primarily at HIV and HCV	
	Cerebrovascular accident (CVA)	Substance-induced (cocaine, AGS)	Supportive care	Associated with 70% likelihood of developing depression
		Hemorrhage due to septic emboli	Same as for endocarditis	
Renal	Heroin or HIV-associated nephropathy	Both present with nephrotic syndrome	Renal biopsy to establish diagnosis Electron microscopy distinguishes diagnosis; ART should be started immediately for HIV-associated nephropathy	Focal and segmental glomerular sclerosis (FSGS) with progression to renal failure in weeks to months
	Glomerulonephritis	HBV, HCV	Treat underlying viral infection	
		Systemic bacterial infection	Same as for endocarditis

Abbreviations: ART, antiretroviral therapy; TB, tuberculosis; TMP/SMZ, trimethoprim/sulfamethoxazole; AGS, amphetamine-group substances; ↓/↑s, decreases/increases; ↓/↑d, decreased/increased; HBV, hepatitis B; HCV, hepatitis C; PCN, penicillin; CNS, central nervous system.

## VIRAL HEPATITIS

Chronic Hepatitis B and C are the most prevalent viral infections among IDUs, particularly HIDUs. They share HIV transmission routes, thereby commonly resulting in co-infection. Chronic HCV infection is the most common co-morbidity among HIDUs, occurring in approximately 20% of all PLWHA and in 60–90% of HIDUs. Although HCV transmission is primarily parenteral,<sup>81</sup> increased HCV sexual transmission has been associated with sex with an IDU among women<sup>82</sup> and traumatic sex practices and concomitant ulcerative sexually transmitted infections (e.g., syphilis, HSV) in men who have sex with men.<sup>83</sup> Incidence of perinatal transmission of HCV increases if the mother is co-infected with HIV.<sup>81</sup>

HIV co-infection among HCV-infected persons accelerates progression to end-stage liver disease (ESLD) and increases risk of hepatocellular carcinoma. A meta-analysis of HCV/HIV co-infected patients suggests cirrhosis develops in approximately 21% patients after 20 years and approximately 49% patients after 30 years of HCV infection<sup>84</sup> and decompensated cirrhosis is a leading cause of hospitalization and death in this population.<sup>85</sup> Among HIDUs, mean age of initiation of injecting is 17 years and HCV transmission typically occurs within the first 2 years of injection<sup>86</sup>; consequently, ESLD-related morbidity and mortality has increased as HIDUs live longer.<sup>87</sup> Moreover, HCV co-infection contributes to development or acceleration of cardiovascular disease,<sup>88</sup> neurocognitive impairment,<sup>89</sup> insulin resistance,<sup>90</sup> and renal insufficiency,<sup>91</sup> emerging co-morbidities that complicate care among PLWHAs.

Factors contributing to accelerated fibrosis progression in HIV/HCV co-infected persons include low CD4 counts, detectable HIV-1 RNA levels, use of hepatotoxic medications, and frequent alcohol use. HIDUs, compared to other PLWHAs, are more likely to present with advanced HIV disease and drink alcohol, thereby accelerating progression to ESLD.<sup>92</sup> Effective provision of ART, despite its potential for medication-associated hepatotoxicity, reduces HCV progression to ESLD.<sup>93</sup> It is recommended that HIV treatment be optimized prior to initiation of HCV treatment.<sup>94,95</sup>

Few HIDUs receive treatment for HCV. Reasons cited include cost, physician reluctance, unsubstantiated concerns about poor treatment adherence, misperception that HCV infection is not harmful, and pessimism about HCV treatment tolerability and efficacy among HIDUs.<sup>96</sup> There is admittedly much less published information about HCV treatment response in HIV/HCV co-infected patients but existing studies suggest a lower likelihood of their achieving a sustained virologic response to HCV treatment.<sup>94</sup> Despite these concerns, a growing number of studies in methadone clinics,<sup>97</sup> primary care settings,<sup>98</sup> and prisons<sup>99</sup> provide support for treating HIDUs for both HIV and HCV. Current therapeutic options for treating co-infected patients, including drug-drug interactions and the management of ESLD with transplantation, remain a challenge. Interested readers should consult more specialized texts.<sup>2,85,99–104</sup>

Chronic hepatitis B affects 10% of HIV-infected individuals worldwide, ranging from 5% in Western countries to 20% in some Asian and African regions where HBV is endemic.<sup>105</sup> In areas of low HBV endemicity, the virus is mostly transmitted through IDU and sexual contact, whereas in highly prevalent regions, HBV is mostly acquired through perinatal transmission.<sup>81</sup> Multiple concurrent hepatic viral infections complicate care among a subset of 3–5% of PLWHA, contributing greatly to poor outcomes.<sup>81</sup> HIDUs who do not have evidence of previous exposure to Hepatitis B should be vaccinated against the disease and counseled about safe injection practices to avoid exposure. All HIDUs requiring HBV treatment should be simultaneously treated with suppressive ART regimens. These regimens should minimally include two antivirals that effectively treat both infections.<sup>81,102</sup>

## TUBERCULOSIS

Tuberculosis (TB) and HIV have been tightly linked since the early years of the HIV/AIDS epidemic. TB has emerged as a leading cause of morbidity and mortality among HIDUs, especially in resource-poor settings. TB incidence has fallen or stabilized among IDUs in many industrialized countries but not in Eastern Europe and countries of the former Soviet Union.<sup>106</sup> Moreover, in many of the most populous countries of Asia, IDU contributes greatly to expanding HIV epidemics and high rates of TB. This awareness has unveiled the daunting challenges (see Box 89.1) confronting successful treatment of TB, HIV/AIDS, and SUDs.<sup>107</sup> The root cause of these epidemiological trends is multifactorial and related to the special challenges in diagnosing and managing both latent and active TB in HIDUs.

### Box 89.1 Critical Issues for Drug Users with TB and HIV Co-infection

- Intensive case finding and enhanced screening for identification of TB and HIV cases early in the course of disease
- Screening for latent tuberculosis infection (LTBI) and provision of isoniazid prophylaxis therapy (IPT)
- Enhanced airborne infection control in clinical care and other congregate settings (e.g., prisons, detention centers, drug treatment programs)
- Screening of all TB patients for HIV
- Screening of all HIV patients for TB
- Training and experience with special TB diagnostic challenges in HIV co-infected patients
- Recognition of the need for and implementation of adequate adherence support, including the use of directly observed therapy and linkage to supervised medication-assisted therapy (e.g., methadone or buprenorphine maintenance)
- Awareness of increasing rates of drug-resistant tuberculosis
- Appreciation of pharmacokinetic drug interactions among therapies to effectively treat substance abuse, HIV and tuberculosis
- Promoting and developing comprehensive, collaborative and integrated services for substance use, TB and HIV prevention and treatment services

Reproduced with permission from Lancet, Altice 2010.<sup>2</sup>

TB co-infection among HIDUs presents special diagnostic dilemmas. HIV-induced immunosuppression confounds diagnosis of latent TB, reducing tuberculin skin testing (TST) and newer interferon-gamma release assay utility; both are increasingly insensitive as immunosuppression progresses. Advanced HIV co-infection also confounds pulmonary TB diagnosis because of negative sputum smears (40–60% of infections), atypical chest radiographs, and high rates of difficult-to-diagnose extrapulmonary TB.<sup>108,109</sup> This is further exaggerated by poor access to care and advanced clinical presentation among HIDUs. When available, TB culture and drug-sensitivity testing requires weeks to months to complete. TB diagnosis among HIDUs is therefore delayed, often unconfirmed, influences treatment decisions and results in increased mortality.

Treatment of TB among HIDUs is also complicated. Contributing factors include additive toxicities, pharmacokinetic interactions, and special strategies needed for assuring treatment success. HIDUs experience increased frequencies of side effects and toxicities from TB and ARTs, likely resulting from the high prevalence of hepatic, renal, neurological, psychiatric, gastrointestinal, and hematologic co-morbidities among IDUs.<sup>35</sup> In terms of pharmacologic interactions, rifampin's effect on selected MAT and antiretroviral agents is particularly problematic.

TB treatment outcomes among HIDUs are less favorable than among other populations, not only because of these drug interactions but also because of structural and behavioral barriers to care. Treatment of SUDs is often prerequisite for successful HIV and TB treatment but lack of access to MAT is common where these co-morbid conditions occur. Stigmatization of HIDUs co-infected with TB further discourages this vulnerable population from accessing care in a timely fashion. Resultant poor adherence to therapy, decreased retention in care, and poor continuity of care between the community and prison setting frequently occurs, with increasing risk for TB and HIV drug resistance. This, in turn, reduces treatment success for both diseases in individual patients and increases transmission of resistant organisms to others. For this reason, the WHO advocates intensified TB case-finding among IDUs in non-medical settings. In addition to MAT, once in treatment, adherence support, directly observed therapy (DOT), and integrated healthcare delivery is strongly recommended and necessary to ensure long-term adherence and reduced morbidity and mortality.<sup>107,110</sup>

TB-associated morbidity and mortality among HIDUs results both from latent TB infection (LTBI), with increasing reactivation from HIV-induced immunosuppression, and from increased transmission in crowded and poorly ventilated settings where HIDUs congregate (e.g., prisons, drug treatment programs, and healthcare facilities). Latent TB reactivation among HIDUs is 9% *annually*, in contrast to a similar *lifelong* risk among HIV-uninfected populations with LTBI. Isoniazid preventive treatment (IPT) of LTBI has been demonstrated to be effective in HIDUs.<sup>111</sup> IPT, however, is prolonged and is associated with increased hepatotoxicity in the setting of HCV infection<sup>112</sup> and poor adherence, both major concerns among HIDUs. ART

also dramatically reduces TB incidence and recurrence among susceptible populations.<sup>113</sup> Prolonged use of IPT (36 months), coupled with ART in non-drug using PLWHA is associated with greater than 90% reduction in incident TB cases in TST+ individuals; however, IPT is less beneficial in TST- patients, and may be detrimental.<sup>114</sup>

On the other hand, treatment of drug-susceptible active pulmonary TB among HIDUs can be highly successful. Standard first-line TB treatment for HIDUs is the same as for others. Early diagnosis, adherence to combination anti-TB agents, and co-administration of ART are necessary components of successful treatment programs. Multiple observational studies demonstrate that ART reduces TB transmission and mortality from HIV/TB co-infection. A randomized clinical trial of integrated versus sequential TB and antiretroviral treatment demonstrated a 56% reduction in all-cause mortality in the integrated arm supporting both early ART initiation and integration of HIV and TB care.<sup>115</sup> Current WHO guidelines recommend initiation of ART among all PLWHA with TB, irrespective of CD4 count, as soon as possible within the initial phase of TB treatment.<sup>116</sup> Coordination and integration of services is crucial to ensure therapeutic success for HIDUs.<sup>110</sup>

Although most TB cases worldwide are susceptible to anti-TB therapy, drug-resistant TB has now emerged as a growing threat.<sup>117</sup> This problem is complicated among HIDUs by decreased TB treatment completion rates, resulting in selection of drug-resistant mutants and increased exposure to congregate settings that facilitate their transmission. Enhanced airborne infection control in congregate settings has been shown to prevent drug-susceptible and drug-resistant TB transmission to HIDUs.<sup>118</sup> Despite confirmed effectiveness of these strategies, their widespread application for HIDUs who frequent congregate settings remains limited.<sup>119</sup> Increasing numbers of cases of extremely drug resistant tuberculosis (XDR-TB) (MDR-TB plus resistance to second-line TB medications) worldwide have renewed global awareness of drug-resistant TB and its individual and public health impact.<sup>117</sup> As compared to drug-susceptible TB, treatment of drug-resistant TB is more complicated because available agents have less potency, increased toxicities, longer treatment duration, greater cost, and limited availability.

## OTHER INFECTIOUS COMPLICATIONS

Bacterial infections account for substantial morbidity and mortality among HIDUs, accounting for up to 25% of deaths.<sup>120</sup> These infections are commonly associated with syringe reuse, non-sterilization of the injection site, and injecting with crack or into sites other than the arm.<sup>121</sup> Injection breaches the natural integument defenses, increasing risk for both vascular and soft tissue injuries by exposing them to pathogens that may cause localized or systemic infections. Commensal staphylococcal and streptococcal species are predominantly involved. High *Staphylococcus* colonization rates among HIDUs, including methicillin-resistant strains of *Staphylococcus aureus*, contribute to

the high prevalence of bacterial infections in IDUs.<sup>122</sup> Methicillin-resistant strains of *Staphylococcus aureus* bacteremia has increased significantly in HIV-infected patients, and is associated with IDU, end-stage renal disease, and low CD4 counts.<sup>123</sup> Poor hygiene, injection of unsterile preparations, and unsterile injecting technique also predispose to infections with other bacterial pathogens such as *Pseudomonas*, clostridial, and candida species.<sup>124</sup>

Unusual bacterial infections and complications may result from contaminated drug or drug solutions. Some drug users crush tablets of prescription drugs, then dissolve and inject them intravenously or subcutaneously, resulting in infusion of filler agents commonly present in tablets including cornstarch, cellulose, or talc. These adulterants can become trapped by the pulmonary capillary bed and result in chronic inflammation and foreign body granulomatosis (e.g., talc lung).<sup>125</sup> These adulterants can also damage the endothelium of heart valves, resulting in increased risk of endocarditis.<sup>126</sup> Heroin and cocaine are often “cut” with various adulterants to enhance mind-altering properties or to substitute for pure drug (e.g., amphetamines, Ritalin, clenbuterol, dextromethorphan, fentanyl, ketamine, lidocaine, LSD [lysergic acid diethylamide], pseudoephedrine, quinine, scopolamine, or xylazine). Fatal outbreaks of wound botulism and other clostridial species, *Bacillus cereus* panophthalmitis, tetanus and aspergillus fungal infections caused by injection of contaminated heroin have been reported.<sup>127–129</sup>

Concomitant drug use portends additional complications to many organ systems, resulting in increased morbidity and mortality and complicating treatment (see Table 89.3). Bacterial infections range from the more prevalent localized skin and soft tissue infections (SSTIs) to less common deep-seated infections including pyomyositis, septic arthritis, osteomyelitis, and endocarditis.<sup>130</sup> IDUs who develop endocarditis are more likely to have tricuspid valve involvement but aortic or mitral valve involvement and HIV infection are associated with increased hospitalization,<sup>131</sup> morbidity, and mortality.<sup>132</sup> Clonal invasive Group A streptococcal infection outbreaks reported in Europe resulted in life-threatening infections among IDUs.<sup>133</sup> A Spanish surveillance study associated these outbreaks with specific environmental (drug-purchase site/dealer, homelessness) and injection-related (injection frequency, sharing paraphernalia) factors.<sup>134</sup> The cost of treating and managing injection-related SSTIs and their complications is considerable.<sup>135</sup> IDUs in the U.S. who sought care for SSTIs have increased risk for subsequent hospitalization and death. Visits for SSTIs therefore represent missed opportunities for preventive care for IDUs.<sup>136</sup>

### NON-INFECTIOUS END ORGAN COMPLICATIONS

Chronic kidney disease is increased among HIDUs and caused by infectious (e.g., HBV, HCV) and non-infectious etiologies, including direct medication-associated kidney damage<sup>137</sup> and, less commonly, heroin-related nephropathy.<sup>138</sup> Predisposing risk factors for chronic kidney disease, including African American race, low socioeconomic status, diabetes, and hypertension are highly prevalent

among HIDUs. Furthermore, proteinuria is more common among HIDU than uninfected IDUs and is associated with progression to end stage renal disease and cardiovascular morbidity.<sup>139</sup>

Cocaine and AGS increase blood pressure and vascular spasm of the coronary and cerebral arteries, resulting in myocardial infarction and cerebrovascular accidents. Atherosclerosis that results in increased cardiovascular disease is reduced by ART, but is accelerated by chronic inflammation from HIV and HCV infections and by some protease inhibitors.<sup>88</sup>

Non-AIDS malignancies are emerging as ART successfully averts development of opportunistic infections. Infection-related cancers (anal and liver cancer, Hodgkin lymphoma) and non-infection-related cancers (e.g., of lung, skin, non-Hodgkin lymphoma) are increasingly reported.<sup>140</sup> European and North American cohort studies, where ART is readily available, remind us that non-AIDS complications are emerging as leading causes of mortality among PLWHAs.<sup>141</sup> Absent from these cohorts is a concentration of HIDUs but these non-AIDS co-morbidities are already straining healthcare delivery issues and are likely to grow with time in regions where injection drug use is rising.

### MENTAL ILLNESS

A thorough discussion of mental illness as it relates to substance misuse and HIV is beyond the scope of this chapter. It should be noted, however, that mental illness among HIDUs is associated with high-risk behaviors,<sup>142</sup> decreased adherence to ART, and HIV clinical progression.<sup>143,144</sup>

## Issues in Special Populations

### WOMEN

Women who inject drugs experience extraordinary stigma and sometimes cultural condemnation. They may face discrimination both because of their drug use and of their gender.<sup>12</sup> Published research to date on female IDUs centers on the concept that women's drug use is driven by and embedded within social relationships. In this social context, specific patterns of injection drug use among women pose exquisitely high risk for acquisition of HIV. Women are more likely than men, for example, to begin injecting at a younger age, to be introduced to injecting by either male sexual partners or other female friends, and to have used other illicit drugs for less time before first injecting.<sup>145–147</sup> Because female IDUs often depend on others to acquire drugs and because they use drugs in dyads, they are more likely to be injected by someone else and to have ever shared needles or other drug paraphernalia.<sup>146–149</sup> As such, women are often “second on the needle” and therefore experience increased risk of exposure to HIV and viral hepatitis.<sup>146,148</sup> This dependency on others to obtain, prepare, and inject drugs perpetuates a power imbalance within relationships in which women have limited autonomy in modifying their drug-use behaviors.<sup>12</sup> They may also be forced to rely on sexual bartering for drugs, further potentiating HIV risk. In this role, women are also subject to increased risk of sexual

and physical intimate partner violence, the prevalence of which is three times higher in drug-involved women than in women who do not use drugs.<sup>150,151</sup> Among female IDUs, violence is considered an independent risk factor for HIV exposure and acquisition.

Drug-dependent women are doubly at risk for HIV because of overlapping sexual and drug networks. While some drug-involved women inject with their sexual partners, others do not inject drugs but have high-risk sexual partners who do. In New York City, for example, recent surveillance data revealed that 8% of heterosexual HIV diagnoses in 2001–2007 were attributed to sex partnerships between male IDU and female non-IDUs.<sup>152</sup> A pooled estimate of the risk of HIV transmission between infected IDUs and their sexual partners was 1 in 2000–5000 heterosexual sex acts.<sup>153,154</sup> These heterosexual IDU sex partnerships were associated with unprotected sex, heavy crack use, incarceration, and poverty, each of which independently contribute to HIV risk.<sup>152</sup>

Treatment of HIV-infected women follows standard guidelines, except during pregnancy in which teratogenic antiretrovirals and single-dose regimens should be avoided.<sup>155,156</sup> A complete discussion of the treatment of HIV in pregnancy and mother-to-child transmission of HIV is beyond the scope of this chapter but is discussed elsewhere in this book. Treatment of SUDs in HIV-infected women is similar to that of their male counterparts but data are sparse on MAT during pregnancy, in part because the topic of drug use in pregnancy is highly stigmatized.<sup>12,147,148,157,158</sup>

## INCARCERATED HIV-INFECTED DRUG USERS

The high rates of HIV among prisoners globally is directly associated with society's approach to controlling illicit drug use. Mass incarceration of drug users has resulted in concentration of HIV/AIDS, TB, and other co-morbidities within prisons compared to surrounding communities.<sup>165</sup> While the single most important strategy in controlling HIV in prison is to stem the rate of incarceration itself,<sup>159</sup> ample evidence suggests that the criminal justice system can be an effective place to identify and treat HIV and SUDs when appropriate services are available.<sup>160</sup>

Incarceration itself increases HIV risk, through a cascade of multiple factors, including disruption of social networks,<sup>161,162</sup> multiple partners and high-risk sexual behaviors that are associated with mass incarceration,<sup>163</sup> and reduced likelihood for gaining meaningful employment or entrance into social service and rehabilitation programs. Inadequate treatment of mental illness and lack of social support puts prisoners at a greater risk of relapsing SUDs and reincarceration.<sup>164</sup> Most incarcerated HIDUs have limited or no access to ART or MAT. When widescale ART is prescribed in prison settings, prison-related HIV mortality achieves parity with the community.<sup>165</sup> Highly structured prison or jail settings may also provide opportunities to initiate treatment for SUDs. Despite a large body of evidence, very few MAT programs transitioning HIDUs from prison to the community have been developed.<sup>166</sup> Treatment benefits may therefore be lost beyond the period of incarceration.<sup>167–169</sup>

## Overcoming Healthcare Disparities in HIV-Infected Drug Users

The life of a drug-dependent patient is often chaotically organized around substance use needs. Access to drugs may replace even the most basic human needs, including food, clothing, shelter, safety, and healthcare. To engage HIDUs in care, health providers should offer integrated medical, psychiatric, and social services in a convenient way. Successful programs for this population have developed some or all of the following characteristics:

- (i) Pharmacologic (e.g., methadone or buprenorphine treatment program)<sup>170</sup> and/or non-pharmacological treatment (e.g., behavioral interventions) for substance use<sup>170,171</sup>
- (ii) Flexible outpatient and community care settings (e.g., walk-in clinics, mobile healthcare programs)<sup>172</sup>
- (iii) Low-threshold sites to engage active users (e.g., syringe exchange sites)<sup>173</sup>
- (iv) Directly administered ART<sup>174,175</sup>
- (v) Intensive outreach and case management services<sup>176,177</sup>
- (vi) Treatment during incarceration<sup>168,178</sup>

## HIV Prevention and Risk Reduction Strategies

The relapsing pattern of drug use and the wide array of associated severe medical consequences require the development of preventive risk reduction strategies. Risk reduction does not promote injection drug use, but seeks to decrease the frequency of adverse events that are related to this practice, including HIV transmission. Risk reduction is based on the underlying principle that injection drug use is a chronic and relapsing disease that may not be cured in the individual or eliminated from society but can be conducted in a way that minimizes harm to the user and others. While complete cessation of drug use remains a laudable goal, reduction in drug use frequency and safer injection practices are more realistic goals for many drug users until abstinence can be achieved. Risk reduction strategies have been effectively incorporated into some drug treatment programs, syringe exchange programs, and safe injection rooms.<sup>179–181</sup>

There are two main types of interventions to decrease injection-related HIV transmission: (i) those that seek to reduce the total number of injections (i.e., quantity) and (ii) those that aim to reduce unsafe injection practices (i.e., quality).<sup>154</sup> Programs designed to reduce the total number of injections include treatment for SUDs and criminal punishment for SUDs. Effective drug treatment, primarily through MAT, is a very effective way to reduce drug-related harm but these therapies do not reach many IDUs. In 126 reporting countries, only 8 per 100,000 IDUs were receiving opioid substitution therapy.<sup>182</sup> Furthermore, even with marked risk reduction in this setting, opioid-dependent drug users may continue to inject, primarily with non-opioids. As such, there is a need for further risk reduction using other methodologies. There is less consistent published data on the reduction of injections with behaviorally based drug treatment interventions. Where MAT coverage is insufficient, it is imperative to have available access to clean needles and syringes.

Needle and syringe exchange programs are critical primary and secondary prevention interventions for IDUs, particularly those who are HIV-infected.

In some countries, primarily in Southeast Asia, efforts to reduce injection-related HIV transmission by dissuading drug use have devolved into criminalization of drug use. As part of extra-judicial systems, drug misusers are detained in closed settings and receive little treatment for SUDs or education about HIV prevention. As such, these systems are ineffective at either curbing HIV transmission within these drug detention centers or preventing relapse to drug use upon release.<sup>154</sup>

Other programs seek to secondarily prevent HIV by reducing unsafe injection practices. Education about hygienic injection practices and the provision of drug use paraphernalia are essential to HIV prevention services. These programs have been shown to be cost-effective in settings with high HIV prevalence.<sup>154</sup> Still, only 8% of IDUs worldwide access needle and syringe exchange programs on an annual basis.<sup>182</sup> In addition to the distribution or exchange of injection equipment, these programs typically include HIV/AIDS education, condom distribution, and referral or enrollment in a variety of drug treatment, medical, and social services.<sup>183</sup> Specifically, some programs provide onsite medical and drug treatment, resulting in reductions in emergency department use by IDUs.<sup>173</sup> Provision of primary medical care services linked to drug-abuse treatment is a way to promote preventive therapies to enhance harm reduction. In this and all other clinical settings, in addition to the treatment of HIV disease and prevention of complications, injection drug users should be routinely screened for Hepatitis B and C, latent *Mycobacterium tuberculosis* infection, syphilis, and other sexually transmitted diseases. They should be offered pneumococcal, influenza, tetanus, and hepatitis B immunization and (when appropriate) prophylaxis for TB.<sup>184</sup>

Effective strategies for secondary HIV prevention in HIDUs should include sexual risk reduction in addition to drug-related risk reduction.<sup>185</sup> This is especially important for female partners of IDUs, for whom sex constitutes the major risk behavior for HIV acquisition. Although better studied in non-IDU populations, sexual risk reduction for serodiscordant couples includes education about and provision of condoms, testing and treating high-risk cohorts for HIV, and reduction of HIV viral load with ART to reduce infectivity.<sup>154</sup> There is limited information available on the provision of ART to HIDUs but, of 47 countries who recently reported, only 4 HIDUs were receiving ART for every 100 in the population.<sup>182</sup> This suggests a need for antiretroviral scale-up to treat HIV among IDUs and decrease HIV transmission among serodiscordant couples.

## Summary

- The drugs most commonly associated with HIV infection worldwide are heroin, cocaine, and amphetamine group substances but both injection and non-injection drug use are associated with increased HIV-related risk-taking.
- HIDUs face numerous social and structural barriers to care, such that any potential benefits of HAART on HIV-related morbidity and mortality are lost because HAART is either not offered or because drug users receive discontinuous care. Furthermore, HIDUs are often labeled as “difficult patients” because HIDUs experience multiple co-morbidities, especially HCV, TB, skin and soft tissue infections, and mental illness.
- Effective strategies for overcoming healthcare disparities for HIDUs include addressing HAART adherence and promoting secondary prevention of HIV. Ample evidence suggests that the criminal justice system (CJS) can be an effective place to identify and treat HIV when appropriate services are available.
- Treatment of substance use disorders is equally vital. Greatest evidentiary support is for methadone and buprenorphine as opiate substitution therapies. Providers should be aware, however, of pharmacological interactions between MAT therapies and HAART.
- Most importantly, to engage HIDUs in care, health providers should offer integrated medical, psychiatric, and social services in a convenient way.

"This page intentionally left blank"

All sexually transmitted infections (STIs) considered together represent one of the common infectious diseases both in developed and developing worlds. STIs are more prevalent in teenagers and young adults of reproductive age group. Of the various STIs, syphilis, gonorrhea, chlamydia, hepatitis B virus, HIV, HPV, and herpes simplex infections carry a potential impact on maternal, fetal, and neonatal health, while other STIs like *T. vaginalis* and bacterial vaginosis (BV) also contribute to adverse pregnancy outcome. With untreated STIs, post delivery infections are more in frequency and severity. Immunological changes occurring during pregnancy like decrease in CMI, Th1 type cytokines, and other proinflammatory cytokines make the woman more susceptible to infections in which Th1 response is important for protection against viral infections as well as infection with intracytoplasmic pathogens.<sup>1,2</sup> Developing targeted interventions to reduce STI related maternal and infant morbidity are critical public health issues. Pregnancy provides an opportunity for screening and treatment of these infections to minimize or eliminate antepartum, intrapartum, and postpartum consequences of most STIs.

### Syphilis in Pregnancy

Syphilis in pregnancy represents an important cause of fetal and neonatal loss in many developing countries. In parts of Africa, the prevalence of syphilis among antenatal clinics has been found to be as low as 1.1% in Nigeria and as high as 17.4% in Cameroon.<sup>3,4</sup> The continued high prevalence of syphilis at delivery has been associated with HIV infection, substance abuse, lack of prenatal care, and treatment failure.<sup>5</sup> However, the rates of syphilis in the US have declined since 1990 and it was a record low of 2.6 cases per 100,000 persons, likewise a record low incidence of congenital syphilis (CS), 20.6 per 100,000 live births in 1998,<sup>6</sup> which further declined to 13.4/100,000 live births in 2000.<sup>7</sup> However, the rate of CS in the US has started to creep back up after plummeting over the last two decades.<sup>1</sup> The incidence of CS has gone up from 8.2 cases per 100,000 live births in 2005 to 10.1 in 2008 with most of the increase having occurred in the

South. CS rates in infants born to black mothers have gone up from 26.6 in 2005 to 34.6 per 100,000 live births in 2008 and now account for half of all CS cases. Since CS is transmitted from mothers with syphilis, CS rates have historically tracked the combined primary and secondary syphilis rate seen in women, which has also started to climb.<sup>8</sup>

### CLINICAL MANIFESTATIONS

Syphilis is divided into various clinical stages—primary, secondary, tertiary, and latent. Latent infection is subdivided into early latent (<1 year duration) or late latent (>1 year duration).

Primary syphilis, which manifests with a painless chancre, follows an incubation period of 10–90 days but it is usually less than 6 weeks. During pregnancy the primary lesions may be of much smaller size or be so located as to go unnoticed. Cervical chancre is more common in pregnancy because of the easy inoculation of the friable cervix. Primary chancre is characterized by a painless, firm ulcer with raised edges and a base with cleaner granulation. It persists for 2–6 weeks and then heals spontaneously, and is often accompanied by nontender, unilateral enlarged and firm inguinal lymph nodes. Six to eight weeks after the primary chancre, secondary syphilis usually appears in the form of a highly variable skin rash. About 15% of the women may still have the remains of chancre when the rash of secondary syphilis appears. The lesions of secondary syphilis may go unnoticed in about one-quarter of the patients. Rash during secondary syphilis does not cause itching and is not bright enough to be noticed to inexperienced eye. In some, the lesions are limited to genitalia as elevated areas or condylomata lata, which occasionally cause vulval ulceration. The disease in an unsupervised pregnant mother may go unnoticed and delivery of a stillborn baby or live baby with severely infected CS may be the only suggestion of the disease in the mother. Recent Centers for Disease Control and Prevention (CDC) data show that 6.5% of US infants with CS in 2008 were stillborn or died within 30 days of birth.<sup>9</sup>

Syphilis in pregnancy may be associated with increased risk of fetal demise, intrauterine growth retardation, and preterm delivery.

However, most frequent and potentially ominous complication of syphilis is congenital infection with *T. pallidum*. Approximate frequency of occurrence of CS is 50% with untreated mother in primary and secondary stage of disease, 40% with early latent and 10% occurrence with late latent and tertiary syphilis.

Clinical manifestation of early CS can be maculopapular rash, snuffles, mucosal patches, hepatosplenomegaly, jaundice, pneumonia, lymphadenopathy, chorioretinitis, and iritis.

### DIAGNOSIS OF MATERNAL SYPHILIS

Non-treponemal Venereal Disease Research Laboratory and rapid plasma reagin tests are accepted as screening diagnostic tools at the first prenatal visit. Because these reagin tests lack specificity, a treponemal test such as fluorescent treponemal antibody absorption test (FTA-ABs) or microhemagglutination assay (TPHA) for detecting antibodies to *T. pallidum* are used to confirm a positive result, especially in women at high risk for syphilis. Enzyme linked immunosorbent assay (ELISA) for syphilis which had a sensitivity and specificity of 100% and 90%, respectively, in a study of 265 specimens has also been used in some centers.<sup>10</sup>

### PATHOPHYSIOLOGY OF CONGENITAL SYPHILIS

Syphilis is neither a new disease nor a newly recognized one. Some of the basic facts of congenital involvement such as Hutchinson triad<sup>11</sup> and Kassowitz's observation in 1846 that the longer a woman has syphilis before pregnancy occurs, the less likely it is that her fetus will die *in utero* or be born with CS<sup>12</sup> have been known for over 100 years.

Despite long history of medical interest in syphilis and its effect on pregnancy outcome, many fundamental questions about the pathophysiology and treatment of syphilis during pregnancy remain unanswered. However, understanding has been advanced by recent reports that delineate the complete sequence of the genome of the syphilis spirochete *Treponema pallidum*, which provide a more precise description of fetal and neonatal infection by use of rabbit infectivity tests, and describe the gestational age distribution of fetal death due to syphilis.<sup>13</sup>

Syphilis is readily transmitted from mother to baby. Spirochetes may easily cross the placenta which results in congenital infection. The probability of transmission of infection to fetus is nearly 100% if mother has early syphilis when there is spirochaetemia,<sup>14</sup> it is 70%, 4 years after acquisition of maternal syphilis.<sup>15</sup> Most infants born to mothers with late latent syphilis are uninfected. The theory that *T. pallidum* is not able to cross the placental barrier until 20 weeks of pregnancy no longer holds true.<sup>16</sup> Using silver stain and immunofluorescence technique, spirochaetes were identified in abortuses as early as after 9–10 weeks of gestation.<sup>17</sup> Using rabbit infectivity test alive *T. pallidum* were identified in amniotic fluid between 14–19 weeks period of gestation.

Hollier et al.<sup>18</sup> in a study on 24 pregnant women with maternal syphilis showed evidence of fetal infection in 16 cases.

Hepatomegaly, fetal ascites, enlarged placenta, and abnormal liver function test were observed in these fetuses. However, this work still fails to address the involvement of the central nervous system (CNS), a critical question that has influenced recommendations for treating CS. Michelow et al.<sup>19</sup> evaluated 140 infants born to mothers with syphilis and showed that 22% has positive result of the rabbit infectivity test on CSF. The evidence suggested that CSF involvement was more likely if maternal syphilis was categorized as secondary or early latent.

Syphilis affects the placenta which becomes large and pale. Microscopically, the villi appear to lose their characteristic arborescent appearance and become thicker and club-shaped. There is marked decrease in the number of blood vessels that in advanced cases almost disappear as a result of endarteritis and proliferation of stromal cells. Related to this, there is increased vascular resistance in the uterine and umbilical artery<sup>20</sup> contributing to intrauterine growth retardation and fetal death.

### SCREENING FOR SYPHILIS IN PREGNANCY

CDC,<sup>21</sup> American College of Obstetricians & Gynecologists (ACOG),<sup>22</sup> and US Preventive Services Task Force (USPSTF), 2009,<sup>23</sup> recommend that all pregnant women should be screened for syphilis during pregnancy at the first prenatal visit. High-risk women should have repeat screening in 3rd trimester. Women who had delivered a non-immune hydropic fetus or experienced a stillbirth or has the diagnosis of hydrops on ultra sound should also undergo screening for syphilis. Women not tested for syphilis during pregnancy should be tested for syphilis at the time of delivery/labor.

### TREATMENT

Centres for Disease Control and Prevention (CDC)<sup>21</sup> recommends treating early syphilis (primary, secondary, or early latent) with a single dose of 2.4 million units of benzathine penicillin G (7.2 million units over three weeks with 2.4 mu weekly for late latent syphilis or latent syphilis of unknown duration).

From retrospective studies it is observed that benzathine penicillin G cures early maternal syphilis and prevents neonatal syphilis in 98% of cases.<sup>24</sup> In UK, specialists favor prolonged parenteral course of procaine penicillin, and in the US, a single injection of benzathine penicillin G is recommended for the treatment of early infectious syphilis. However, the superiority of one regimen over the other has not been proved. CDC guidelines for the treatment of syphilis in pregnancy recommend the same dosage schedule of benzathine penicillin G as for non-pregnant adults. Some recommend a second dose of benzathine penicillin G, 2.4 million units IM one week after the initial dose, especially for women in the third trimester or for women with secondary syphilis during pregnancy. (For more treatment details refer to Chapter 36 on Infectious Syphilis.)

A review of the success of maternal treatment to prevent CS by stage of infection showed that treatment according to CDC recommendations was 100% effective in preventing CS in all the

27 cases of primary and 136 cases of late/latent syphilis and it was 94.7% effective in 71 of the 75 cases of secondary syphilis.<sup>25</sup>

Walkar et al.<sup>26</sup> in a Cochrane review in 2001 concluded that although there is no doubt that penicillin was effective in treating maternal syphilis and in preventing CS, there was uncertainty about the optimal treatment regimen.

Another study by Wendel et al. in 2002<sup>27</sup> concluded that the available evidence did not indicate that any regimen was more effective than 2.4 million units of benzathine penicillin G for treating early syphilis. Watson-Jones et al.<sup>28</sup> in a study on 1688 pregnant women reported that there was no increased risk of adverse pregnancy outcome in women treated with single dose of benzathine penicillin as compared with seronegative women. This was an important observation since other works had suggested that pregnant women with syphilis who received more than 2–3 doses of benzathine penicillin have better pregnancy outcome than women who receive only one dose.<sup>29,30</sup>

The treatment of syphilis in pregnancy can lead to Jarisch–Herxheimer reaction. In a study of 50 pregnant women who received treatment, 40% experienced Jarisch–Herxheimer reaction and 13 developed regular uterine contractions. Although all resolved without the precipitation of labor, 12 developed variable deceleration of fetal heart rate tracings.<sup>31</sup>

Other antibiotics are also effective against syphilis. Tetracyclines are effective, but are contraindicated in pregnancy because of the discoloration of fetal decidua teeth. Erythromycin is thought to be effective but crosses the placenta poorly, and there have been reports of CS occurring despite “adequate” therapy with erythromycin.<sup>32</sup>

The management of women allergic to penicillin is based on observational studies. Patients with a history of penicillin allergy can be skin tested to confirm the risk of an IgE mediated allergic reaction to penicillin. If skin tests are reactive, penicillin desensitization should be undertaken and then followed by penicillin treatment. The consequences for the fetus of mothers with failed desensitization are unclear. UK guidelines recommend erythromycin therapy and follow-up of the baby. Cephalosporins such as ceftriaxone and newer macrolide antibiotics like azithromycin may prove useful but have not been adequately evaluated.

## DIAGNOSIS AND TREATMENT OF CONGENITAL SYPHILIS

In resource-poor settings the diagnosis of CS is largely based on the use of Venereal Disease Research Laboratory or rapid plasma reagin serological tests.<sup>33</sup> However, these tests detect IgG, which may be passively transferred transplacentally from mother to fetus and interpretation of a positive test is difficult. A comparison of maternal titers with infant's titers may be helpful to some extent. A four-fold higher or rising titer in infant is considered as significant.

Immunoblot may be helpful in diagnosing CS. The value of tests like a lumbar puncture or bone radiograph in asymptomatic infants is doubtful, as the former has a low sensitivity in

asymptomatic infants and the radiological changes are found only in about 20% infants.<sup>33</sup>

In developed countries, guidelines recommend that treatment decision be based on:

- Identifying syphilis in the mother
- Confirming the adequacy of maternal treatment
- Identifying clinical, laboratory or radiographic evidence of syphilis in the infant;
- Comparing maternal non-treponemal serological titers (at delivery) with the infant's non-treponemal titres.<sup>33</sup>

Symptomatic infants or those with abnormal spinal fluid examination can be treated with aqueous penicillin G, 100,000–150,000 IU/kg/day given IV in two to three divided doses each day for at least 10 days, or procaine penicillin G 50,000 IU/kg IM daily for a minimum of 10 days. Asymptomatic seropositive infants with normal CSF can be treated with a single dose of benzathine benzylpenicillin 50,000 IU/kg administered IM. Infants born to mothers treated with erythromycin should be treated as if they have CS.

## Gonococcal Infection in Pregnancy

Next to genital chlamydial infections, gonococcal infection is the most frequently reported sexually transmitted disease in the US.<sup>34</sup> The prevalence of gonococcal infection during pregnancy varies but may be as high as 7% and reflects the risk status of the population.<sup>35,3</sup> Risk factors include being single, adolescent, poverty, drug abuse, prostitution, other STIs and, lack of prenatal care. Gonococcal infection is also a marker for concomitant chlamydial infection in about 40% of the infected pregnant women,<sup>36</sup> while overall prevalence of coinfection varies from 30 to 46%.<sup>37,38</sup>

In most pregnant women, gonococcal infection is limited to the lower genital tract, including the cervix, urethra, and periurethral, and vestibular glands. Acute salpingitis is rare but develops if the cervical infection ascends before the obliteration of the uterine cavity through the fusion of the chorion and decidua at 12 weeks. Pre-existing infection can cause a tubo-ovarian abscess, but this is even rarer.

Gonococcal infection in any trimester may have deleterious effects on the pregnancy outcome. There is an association between untreated gonococcal cervicitis and septic spontaneous abortion or infection after induced abortion.<sup>39</sup> Preterm delivery, prematurely ruptured membranes, chorioamnionitis, and postpartum infection are more common in women with *Neisseria gonorrhoeae* detected at delivery.<sup>40</sup> Attributable risk for preterm birth has been reported as 14%.<sup>41</sup> Expectant management of the culture-positive woman has been recommended even with prematurely ruptured membranes as long as antimicrobial treatment was given promptly.<sup>42</sup>

There is some evidence that pregnancy alters the clinical presentation of gonococcal infections. Increased rates of oropharyngeal and anal infections in pregnancy have been reported.<sup>43,44</sup> The increased incidence of non-cervical infection may be due to altered sexual practices because of pregnancy, cultural

customs or both. It is also interesting that pregnant women account for a disproportionate number (7–40%) of disseminated gonococcal infections<sup>44,45</sup> which is caused by hematogenous spread of *N. gonorrhoeae* from the primary site. Pregnancy, as well as menses and terminal component complement deficiencies may also increase the risk for disseminated gonococcal infection as a result of endometrial exposure of submucosal vessels to the infecting organisms.<sup>46,47</sup> Disseminated gonococcal infection typically manifests as arthritis, tenosynovitis and dermatitis but can also present as perihepatitis. Rarely endocarditis, meningitis and osteomyelitis occur. Skin lesions appear initially as small vesicles that subsequently become pustules and develop a hemorrhagic base.<sup>48</sup>

### GNOCOCCAL INFECTION AMONG NEONATES AND INFANTS

Gonococcal infection among infants usually results from exposure to infected cervical exudates at birth. It is usually an acute illness that manifests 2–5 days after birth. The prevalence of infection among infants depends on the prevalence of infection among pregnant women, whether pregnant women are screened for gonorrhea and whether newborns receive ophthalmia prophylaxis. The most severe manifestations of *N. gonorrhoeae* infection in newborn are ophthalmia neonatorum and sepsis, which can include arthritis and meningitis. Less severe manifestations include rhinitis, vaginitis, urethritis, and infection at sites of fetal monitoring. Identifying and treating this infection is especially important because ophthalmia neonatorum can result in perforation of the globe of the eye and blindness.

### DIAGNOSIS

Because of the lower sensitivity (as compared to symptomatic men) Gram stain of endocervical, pharyngeal or rectal specimens is not sufficient to detect infection and therefore is not recommended. Specific testing for *N. gonorrhoeae* is recommended because of the increased utility and availability of highly sensitive and specific testing methods and a specific diagnosis might enhance partner notification.

Specific diagnosis of infection with *N. gonorrhoeae* may be obtained by testing endocervical, vaginal or urine specimens. Culture, nucleic acid hybridization tests and NAAT are available for detection of genitourinary infection with *N. gonorrhoeae*.<sup>49</sup>

In all cases of neonatal conjunctivitis exudates should be cultured for *N. gonorrhoeae*. A definite diagnosis is important because of the public health and social consequences of a diagnosis of gonorrhea.

### TREATMENT

Pregnant women should not be treated with quinolones or tetracyclines. Those infected with *N. gonorrhoeae* should be treated with a recommended regimen like ceftriaxone 125 mg, or 250 mg IM in a single dose or cefixime 400 mg orally in a single dose. Women who cannot tolerate a cephalosporin should be administered a single 2 g dose of spectinomycin IM. Either

azithromycin or amoxicillin are recommended for a treatment of presumptive or diagnosed co-infection with *C. trachomatis* infection during pregnancy.

Though single-dose treatment is sufficient for uncomplicated infection, treatment should last not less than 7 days for disseminated gonococcal infection. For gonococcal endocarditis, therapy should be continued for at least 4 weeks and for meningitis for 10 to 14 days. Endocarditis rarely complicates pregnancy and it may be fatal.<sup>50</sup>

Recommended regimen for gonococcal conjunctivitis is ceftriaxone 25–50 mg/kg IV or IM in a single dose, not to exceed 125 mg. Topical antibiotic therapy alone is inadequate and is unnecessary if systemic treatment is administered.

It is also recommended that the mother and infant be evaluated for concomitant chlamydial infection. Isolation is recommended until treatment for 24 hours. Both parents should also be investigated appropriately and treated.

### Bacterial Vaginosis

Bacterial vaginosis (BV) is defined as replacement of normal, healthy vaginal lactobacilli by a characteristic set of genital anaerobes, mycoplasmas, and *Gardnerella vaginalis*. BV has been detected among 10–41% of women in various studies.<sup>51–54</sup> Women seen in sexually transmitted disease clinics have the highest prevalence of BV, up to 64%.<sup>55,56</sup> Studies in pregnant women demonstrate prevalence for BV similar to those found among the non-pregnant populations.<sup>57–59</sup> 50% of cases with BV resolve spontaneously during pregnancy.<sup>60–61</sup> Symptoms include vaginal discharge, pruritus, or malodor although half of the women are asymptomatic.<sup>62–64</sup>

### OBSTETRICAL COMPLICATIONS

Considerable information from around the world links BV directly to a number of serious obstetrical complications, including spontaneous abortion, preterm birth, preterm labor, preterm premature rupture of membranes (PROM), amniotic fluid infection, postpartum endometritis, and postcaesarean wound infections. Risk ratios (RR) range between 1.1 and 7.3 in these studies and have been overwhelmingly significant.<sup>65–67</sup> Most importantly, BV represents a potentially preventable risk factor for these common and costly complications of pregnancy.

### DIAGNOSIS

BV can be diagnosed by the use of clinical or Gram stain criteria. Clinical criteria require three of the following symptoms or signs:

- A homogeneous, white, non-inflammatory discharge that smoothly coats the vaginal walls
- The presence of clue cells on microscopic examination
- pH of vaginal fluid greater than 4.5
- Fishy odor of vaginal discharge before or after the addition of 10% KOH (the whiff test).

A Gram stain is used to determine the relative concentration of the bacterial morphotypes characteristic of the altered flora of

BV, which is an acceptable laboratory method for diagnosing BV. Culture of *G. vaginalis* is not recommended because it is not specific. However, quantitative measurements of *G. vaginalis* using specific DNA probes can serve as a useful aid in diagnosing BV.<sup>68</sup> Cervical Pap tests have limited clinical utility for the diagnosis of BV because of low sensitivity. Other commercially available tests that may be useful for the diagnosis of BV include a card test for the detection of elevated pH and trimethylamine which is produced by anaerobic bacteria and *Mobiluncus* spp.

## SCREENING

The recent awareness of the possible adverse sequelae of BV infection has led to more attention to the screening and treating of women for this condition during pregnancy. An economic model linking perinatal conditions to BV from evidence in the literature to resultant hospital charges concluded that the direct costs of preterm labor, preterm delivery, low birth weight, and other complications associated with BV totaled nearly \$1.0 billion.<sup>67</sup> However, asymptomatic women or women without risk factors do not need routine screening and treatment.<sup>69,70</sup>

## TREATMENT

All pregnant women who have symptomatic disease require treatment. Some specialists prefer using systemic therapy to treat possible subclinical upper genital tract infection. Treatment of BV in asymptomatic women at high risk for preterm delivery has reduced incidence of preterm delivery in three of four randomized controlled trials.<sup>71–74</sup> Recommended treatment is metronidazole 500 mg orally twice a day for 7 days or metronidazole orally 250 mg three times a day for 7 days or clindamycin 300 mg orally twice a day for 7 days. However, concerns have been raised that metronidazole treatment may increase preterm birth in certain populations (often at high doses) up to two times.<sup>75,76</sup>

The treatment of the male partner remains controversial.<sup>77</sup> General clinical trials indicate that a woman's response to therapy and the likelihood of relapse or recurrence are not affected by the treatment of her sex partner(s).

## Trichomonas Infection

Trichomoniasis is caused by the protozoan *T. vaginalis*. Many infected women have symptoms characterized by diffuse, malodorous, yellow green vaginal discharge with vulvar irritation. However, some women have minimal or no symptoms on vaginal examination, in many others vaginal mucosa is erythematous and punctate hemorrhages may be present on the cervix (strawberry cervix).

## DIAGNOSIS

*T. vaginalis* are found readily in a wet mount of vaginal secretion as flagellated, ovoid, motile organisms. The sensitivity of this method is generally considered to be about 85%. *Trichomonas*

are identified most accurately by culture using Diamond medium; however, DeMeo et al. have shown that a DNA probe test was 90% sensitive and 99.2% specific.<sup>78</sup>

Other FDA cleared tests for trichomoniasis in women include OSOM *Trichomonas* Rapid Test and Affirm TMVP III test. The results of OSOM *Trichomonas* tests are available in approximately 10 minutes. Vaginal culture is more sensitive than the direct microscopy of vaginal secretions, as it will detect up to 50% of even asymptomatic vaginal infections. Vaginal fluid should be screened microscopically for *Trichomonas vaginalis* in patients with signs and symptoms of vaginitis and in women with an increased risk of preterm birth.

## EFFECT ON PREGNANCY AND NEONATES

Infection with *Trichomonas vaginalis* has been associated with an increased risk of preterm delivery, premature rupture of membranes, and maternal puerperal morbidity.<sup>79–81</sup> However, data do not suggest that metronidazole treatment results in reduction in perinatal morbidity. Some trials even suggest the possibility of increased prematurity or low birth weight after metronidazole treatment. Limitations of the studies prevent definite conclusions regarding risk of treatment.<sup>82</sup> Treatment of *T. vaginalis* might relieve symptoms of vaginal discharge in pregnant women and might prevent respiratory or genital infection of the newborn and further sexual transmission. Clinicians should counsel patients regarding the potential risk and benefits of treatment. Some specialists would defer therapy in asymptomatic pregnant women until after 37 weeks gestation. In addition, pregnant women should be provided careful counseling regarding condom use and the continued risk of sexual transmission.

Neonatal infection with *Trichomonas vaginalis* is detected very infrequently. The vaginal mucosa of female neonates is susceptible to infection or colonization with *Trichomonas* due to the maternal estrogenic influence. However, this is reversed within 3–4 weeks after birth. Purulent vaginitis and urinary tract infection have been reported in neonates born to untreated mothers.<sup>83</sup>

## TREATMENT

Women may be treated with 2 g of metronidazole or Tinidazole in a single dose orally. Alternative regimen is metronidazole 500 mg orally twice daily for 7 days. Metronidazole is pregnancy category B drug. Multiple studies and meta-analyses have not demonstrated a consistent association between metronidazole use during pregnancy and teratogenic or mutagenic effects in infants.<sup>84–86</sup> Tinidazole in pregnancy is category C drug and its safety in pregnant women has not been well-evaluated.

In lactating women who are administered metronidazole, withholding breastfeeding during treatment and for 12–24 hours after the last dose will reduce the exposure of metronidazole to the infant. While using tinidazole, interruption of lactation is recommended during treatment and for 3 days after the last dose.

## Chlamydia Trachomatis

*Chlamydia trachomatis* is an obligate intracellular bacterium that has several serotypes, including those that cause lymphogranuloma venereum. The most commonly encountered strains are those that attach only to columnar or transitional cell epithelium and cause cervical infection. *Chlamydia trachomatis* is one of the most common sexually transmitted pathogens in the obstetric population, with 2–20% of the pregnant women being infected.<sup>87</sup> In Canada, a major increase in reported chlamydial infections occurred between 1984 (3.2 cases per 100,000) and 1994 (188 cases per 100,000), probably reflecting the improved screening and reporting.<sup>88</sup> *C. trachomatis* infections result in significant morbidity with concomitant social and economic costs. Left untreated, an affected pregnant patient may: (i) pass the organism to her baby at delivery, (ii) develop postpartum endometritis, salpingitis leading to pelvic inflammatory disease, ectopic pregnancy, and infertility (iii) contribute to horizontal spread throughout the community, and (iv) experience possible adverse obstetric outcomes such as preterm delivery, low birth weight, or premature rupture of membranes.<sup>89–93</sup> Debate exists regarding screening for chlamydial infection during pregnancy. National Institute for Health and Clinical Excellence Guidelines of UK<sup>94</sup> do not recommend chlamydial screening during pregnancy whereas the US guidelines do.<sup>95</sup>

### DIAGNOSIS

Diagnosis of *Chlamydia trachomatis* infection in women can be made by testing urine or swab specimen collected from endocervix or vagina. Culture, direct immunofluorescence, EIA, nucleic acid hybridization tests, and NAATs are available for the detection of *Chlamydia trachomatis* on endocervical and male urethral swab specimens.<sup>49</sup> NAATs are the most sensitive tests for these specimens and are FDA cleared for use with urine and some tests are cleared for use with vaginal swab specimens.

### PERINATAL TRANSMISSION

Infection in the mother is mostly subclinical or asymptomatic but at times may cause severe clinical syndromes that include urethritis, mucopurulent cervicitis, and acute salpingitis.

Vertical transmission of *C. trachomatis* generally occurs during labor and delivery with a frequency varying from 23% to 70%. The high prevalence of neonatal conjunctivitis (11–50%) and neonatal pneumonia (3–16%) has been reported among infants exposed at birth.<sup>96–98</sup>

### TREATMENT

Doxycycline, ofloxacin, and levofloxacin are contraindicated in pregnant women. However, clinical experience and studies suggest that azithromycin is safe and effective.<sup>99–101</sup> Repeat testing (preferably by a NAAT) 3 weeks after completion of therapy is recommended for all pregnant women to ensure cure, considering the sequelae that might occur in the mother

and neonate if the infection persists. Recommended regimen is Azithromycin 1 g orally in a single dose or amoxicillin 500 mg orally three times a day for 7 days. Alternate regimens are erythromycin base 500 mg orally four times a day for 7 days or erythromycin base 250 mg orally four times a day for 14 days or erythromycin ethylsuccinate 800 mg orally four times a day for 7 days or erythromycin ethylsuccinate 400 mg orally four times a day for 14 days. Erythromycin estolate is contraindicated during pregnancy because of drug-related hepatotoxicity. The frequent gastrointestinal side effects associated with erythromycin might discourage patient compliance and may require alternate regimens. The lower dose of erythromycin for 14 days may be considered if gastrointestinal tolerance is a concern. In countries where the drug is available, josamycin seems safe and efficacious and might also be considered.<sup>102,103</sup>

## Hepatitis B Virus

Hepatitis B virus (HBV) is endemic in many parts of the world particularly in Asia, South America, Southern Europe, and Africa.<sup>104</sup> This infection is a major cause of acute hepatitis as well as its serious sequelae, namely chronic hepatitis, cirrhosis, and hepatocellular carcinoma. The course of hepatitis B infection in the mother does not seem to be altered by pregnancy. Fulminant hepatitis may occasionally complicate hepatitis B infection but it does not seem to be more prevalent during pregnancy.

Sexual transmission is the most common mode of transmission in addition to infection by transfusion of blood and its products and intravenous drug use. Sexual transmission accounts for most adult HBV infections in the US.<sup>105</sup> Approximately 25% of the regular sexual contacts of infected individuals will become seropositive.<sup>106</sup>

10–20% of women seropositive for HBsAg transmit the virus to their neonates in the absence of immunoprophylaxis. In women who are seropositive for both HBsAg and HBeAg, vertical transmission is approximately 90%.<sup>106</sup> In patients with acute hepatitis B, in the first trimester vertical transmission occurs in up to 10% of neonates, and in 80–90% of neonates when it occurs in the third trimester.<sup>106</sup>

HBV infection does not appear to cause birth defects, but there appears to be a higher incidence of low birth weight among infants born to mothers with acute infection during pregnancy.<sup>107</sup> In one small study acute maternal hepatitis (type B or nontype B) had no effect on the incidence of congenital malformations, stillbirths, abortions, or intrauterine malnutrition. However, acute hepatitis in the mother did increase the incidence of prematurity.<sup>108</sup>

The presence of HBsAg indicates ongoing HBV infection, and in newly infected persons, HBsAg is the only serologic marker detected during the first 3–5 weeks after infection. In persons who recover from HBV infection, HBsAg is usually eliminated from the blood in 3–4 months, and anti-HBs antibodies develop.<sup>109</sup>

Pregnancy is not a contraindication to vaccination. When exposed to a person who has active hepatitis B infection, pregnant patient should receive vaccination as well as immune globulin. When exposed to a person with chronic HBV infection, only

vaccination is required. Babies born to hepatitis B carriers should receive hepatitis vaccine and hepatitis B immune globulin (HBIG) within 12 hours of birth.

## SCREENING

All pregnant women should be tested for hepatitis B surface antigen at first prenatal visit. Women admitted for delivery who have not had prenatal HBsAg testing should have blood drawn at delivery for testing.<sup>109</sup> Routine follow-up testing later in pregnancy is not necessary except in special circumstances such as exposure to a patient with hepatitis or a patient with high-risk behavior (parenteral drug abuse).<sup>110</sup>

## TREATMENT

The treatment of acute HBV infection is supportive. Patients should be hospitalized if they have coagulopathy, encephalopathy, or severe debilitation.

Persons with chronic hepatitis B should be referred to healthcare professionals with experience in the treatment of hepatitis B with alpha-interferon or lamivudine. Interferon does not appear to adversely affect the embryo or fetus. However, the data is limited, and the potential benefits of interferon use during pregnancy should clearly outweigh possible hazards.<sup>111–113</sup> Initial data do not suggest that lamivudine is teratogenic.<sup>114</sup> Lamivudine has been used in the latter half of pregnancy in an attempt to prevent perinatal transmission of hepatitis B virus infection with mixed success.<sup>115,116</sup>

## DELIVERY

Although cesarean delivery has been proposed as a means of reducing mother-to-child transmission of HBV,<sup>117</sup> the mode of delivery does not appear to have a significant effect on the interruption of HBV maternal-baby transmission when vaccine and passive immune globulin is given.<sup>118</sup> Delivery by cesarean section for the purpose of reducing mother-to-child transmission of HBV is not presently recommended by either the CDC<sup>105</sup> or the ACOG.<sup>106</sup>

## BREAST FEEDING

With appropriate hepatitis B immunoprophylaxis, breast-feeding poses no additional risk for transmission from infected hepatitis B virus carrier mothers.<sup>119,120</sup>

## Herpes Simplex Virus

Two types of herpes simplex virus (HSV) have been distinguished based on immunological differences. Type 1 is responsible for most non-genital herpetic infections but frequently involves the genital tract. Type 2 virus is recovered almost exclusively from the genital tract and is transmitted in most of the instances by sexual contact. The incidence of antibodies specific for type 2 herpes virus increases with age and varies considerably with the population studied.

Five percent of all women of childbearing age report a history of genital herpes, and up to 30% have antibodies to herpes simplex virus 2 (HSV-2). 2% of women acquire genital HSV during pregnancy. The incidence of neonatal herpes varies considerably in international studies (about 1:3200 births in the US and 1:60,000 in the UK). Untreated neonatal HSV infection is associated with a mortality of 60%, and even with early and appropriate treatment, survivors experience considerable disability.<sup>121</sup>

## CLINICAL FEATURES AND COURSE DURING PREGNANCY

With primary infection, the typical incubation period of 3–6 days is followed by a papular eruption with itching or tingling which then becomes painful and vesicular with multiple vulvar and perineal lesions that may coalesce. Inguinal adenopathy may be severe. Transient systemic influenza-like symptoms are common and are presumably caused by viremia. Occasionally hepatitis, encephalitis, or pneumonia may develop. Freiden et al. in 1990 reported six cases of maternal encephalitis complicating pregnancy, only two women survived.<sup>122</sup> Although commonly involved in primary disease, cervical involvement is less frequent with recurrent infections.<sup>123,124</sup> Subclinical shedding of HSV-2 occurred in 55% of patients during a mean follow-up of 105 days and lasted for a mean of 1.5 days and often followed a symptomatic recurrence.<sup>125</sup>

Asymptomatic viral shedding is episodic and brief, usually lasting 24–48 hours. 1–2% of pregnant women with a history of recurrent HSV infection have asymptomatic shedding at the time of delivery. Co-infection with HIV may increase asymptomatic shedding of HSV.<sup>126</sup>

Approximately, 80% of young women with recently acquired genital herpes infection will have an average of 2–4 symptomatic recurrences during pregnancy.<sup>123–127</sup> Concomitant cervical shedding is identified in about 15% of women with clinically evident vulvar recurrences. Approximately 10% of the recurrences in pregnancy are asymptomatic, and these are more frequently around the perineum than the cervix. The incidence of positive cultures at any time during pregnancy or at delivery for women who had herpes during non-pregnant time is only 1–2%. Although clinical recurrences appear to be slightly more common in late pregnancy, asymptomatic cervical shedding of herpes virus is unaffected by the duration of pregnancy. Additionally, “remote recurrences,” that is, those on the buttocks, back, thigh, and anus, have low rates of concomitant cervical virus shedding and this safely allows consideration for vaginal delivery.<sup>124–127</sup>

## PERINATAL TRANSMISSION OF HSV

HSV can be vertically transmitted to the infant before, during, or after delivery, although intrapartum transmission accounts for most cases. Maternal age of less than 21 years is a risk factor for vertical transmission.<sup>128</sup>

Approximately 5% of all cases of neonatal HSV infection result from *in utero* transmission. With primary infection, hematogenous spread can produce a spectrum of findings such

as microcephaly, microphthalmia, intracranial calcifications, and chorioretinitis.

Intrapartum transmission accounts for most neonatal infections and occurs with passage of the infant through an infected birth canal. The use of a fetal-scalp electrode increases the risk for intrapartum transmission.<sup>128</sup> From 75% to 90% of infants with neonatal HSV are born to infected asymptomatic mothers who have no known history of genital HSV. Postnatal transmission of HSV can occur through contact with infected parents or healthcare workers.

## NEONATAL INFECTION

Newborn infection has three forms: disseminated, localized, and asymptomatic. Nearly 50% of infected neonates are preterm and their risk of infection correlates with whether there is primary or recurrent maternal infection. Nahmias et al. reported a 50% risk of neonatal infection with primary maternal infection but only 4–5% with recurrent infection and the rates being in between with non-primary first episode.<sup>129</sup> Localized infection is usually associated with a good outcome. Conversely, even after treatment with acyclovir or vidarabine, disseminated neonatal infection is associated with a mortality of at least 60%. Significant serious ophthalmic and CNS damage has been identified in at least 50% of the survivors.<sup>130</sup>

## DIAGNOSIS

HSV culture has long been the criterion standard for diagnosis of HSV infection, with a sensitivity of 70% and a specificity of nearly 100%. The Tzanck smear is an older test that is no longer used because of the large number of both false-positive and false-negative results. Polymerase chain reaction (PCR) is a molecular test that is being increasingly used and that may ultimately replace HSV culture as the standard.<sup>131–133</sup>

## ANTIVIRAL THERAPY

Acyclovir, a nucleoside analogue, was the first antiviral therapy approved for the treatment and prevention of HSV infection. Valacyclovir and famciclovir have been labeled as category B drugs. Recommended regimens for first clinical episode of genital herpes is:

Acyclovir 400 mg orally three times a day for 7–10 days  
OR Acyclovir 200 mg orally five times a day for 7–10 days  
OR Famciclovir 250 mg orally three times a day for 7–10 days  
OR Valacyclovir 1 g orally twice a day for 7–10 days.

Recommended regimen for episodic therapy for recurrent genital herpes is Acyclovir 400 mg orally three times a day for 5 days  
OR Acyclovir 800 mg orally twice a day for 5 days  
OR Acyclovir 800 mg orally three times a day for 2 days  
OR Famciclovir 125 mg orally twice daily for 5 days  
OR Famciclovir 1000 mg orally twice daily for 1 day  
OR Valacyclovir 500 mg orally twice a day for 3 days  
OR Valacyclovir 1.0 g orally once a day for 5 days.

In 1984, the manufacturer of acyclovir, in conjunction with the CDC, established a registry monitoring the safety of the drug.

The registry was closed in 1999. In that time, 1129 acyclovir-exposed pregnancies were reported to the registry; 712 of these occurred in the first trimester. Additionally, 56 valacyclovir-exposed pregnancies were reported; 14 of these occurred in the first trimester.

No increase in the number of malformations occurred with acyclovir, and no pattern of birth defects emerged. Too few cases of valacyclovir-exposed pregnancies precluded the drawing of any meaningful conclusions. Thus, acyclovir appears to be relatively safe to use during pregnancy and should be prescribed as medically indicated.

Proposed 2010 European Guidelines for management of genital herpes also state that women with first episode genital herpes should be treated in line with her clinical condition and will often involve the use of either oral or intravenous acyclovir in standard doses. For recurrent HSV in early pregnancy continuous or episodic therapy is not recommended and should be avoided. Clinicians are on occasion obliged to use therapy for severe and complicated disease and a case-by-case assessment should be made. Newer antivirals should be avoided and the dose of acyclovir titrated down to the minimum effective level.<sup>134</sup>

## STRATEGIES TO PREVENT VERTICAL HSV TRANSMISSION

### Antiviral Suppression for Gravidas with First-Episode Infections during Pregnancy

Scott et al. randomized 46 gravidas with first genital outbreak during pregnancy to receive either acyclovir (400 mg tid) or placebo beginning at 36 weeks' gestation. Patients receiving acyclovir experienced a significant reduction in the percentage of HSV recurrences at delivery (36% vs. 0%) and cesarean deliveries for HSV (36% vs. 0%).<sup>135</sup>

### Antiviral Suppression for Gravidas with a History of Genital HSV

In 1998, Brocklehurst and colleagues performed a double-blind placebo-controlled trial that involved 63 women with a history of recurrent HSV infection.<sup>136</sup> These women were randomized to receive either acyclovir (200 mg qid) or placebo, both beginning at 36 weeks' gestation. No infant in either group developed neonatal HSV, and no gravida experienced toxicity from acyclovir. A 2003 meta-analysis in 799 gravidas also showed that after suppressive therapy there was significant decrease in recurrent HSV infection at delivery, caesarean deliveries for HSV and asymptomatic HSV shedding at delivery.<sup>137</sup> Cochrane Database of Systematic Reviews 2008 (which included 1249 participants) concluded that women with recurrent genital herpes simplex virus should be informed that the risk of neonatal herpes is low. There is insufficient evidence to determine if antiviral prophylaxis reduces the incidence of neonatal herpes. Antenatal antiviral prophylaxis reduces viral shedding and recurrences at delivery and reduces the need for cesarean delivery for genital herpes.

Limited information exists regarding the neonatal safety of prophylaxis. The risks, benefits, and alternatives to antenatal prophylaxis should be discussed with women who have a history and prophylaxis initiated for women who desire intervention.<sup>138</sup>

In 2007, the ACOG published a practice bulletin regarding HSV in pregnancy.<sup>139</sup> Their conclusions were as follows:

- Women with active, recurrent genital herpes should be offered suppressive viral therapy at or beyond 36 weeks of gestation.
- Cesarean delivery is indicated in women with active genital lesions or prodromal symptoms
- Routine HSV screening of pregnant women is not recommended.

## Human Papillomavirus Infection

Anogenital warts are caused by the human papillomavirus (HPV) of which many subtypes have been identified. The subtypes most commonly associated with the genital warts are types 6 and 11, but warts may also be caused by oncogenic types 16 and 18.<sup>140</sup> Women appear to be more likely to manifest HPV infection as symptomatic warts during pregnancy than at other times. Warts are the only manifestation of HPV infection but many women (and men) are infected with HPV in the genital area and will never develop warts. The prevalence of HPV infection in pregnant women has been variously estimated at 5–15%.<sup>141–144</sup> It has been demonstrated that HPV can be transmitted from mother-to-child although the full clinical significance of this for the child is relatively poorly understood.<sup>145</sup> Anogenital warts and juvenile laryngeal papillomatosis are better recognized.<sup>146</sup>

Juvenile onset recurrent respiratory papillomatosis (JORRP) is a benign condition caused by human papillomavirus, usually subtypes 6 and 11 and presents as papilloma in the respiratory tract from the nasal vestibule to the lung tissue in infants and children. Hoarseness of voice and symptoms of obstruction of upper airway tract are the presenting features. Maternal condyloma is the usual source of infection and is found in 50% of the mothers giving birth to JORRP babies.<sup>147</sup> A recent retrospective cohort study has shown that children born to mothers with a history of genital warts have a 231.4 times higher risk of JORRP than those with no such history. In women with genital warts, delivery time of more than 10 hours was associated with a two-fold greater risk of disease. Cesarean delivery was not found to be protective against JORRP.<sup>148</sup>

Oligonucleotide probes specific to each of the five HPV strains have been used to prove the consonance of maternal virus and virus in the newborn. A study on 301 pregnant women with papilloma virus reported that the overall transmission for 16/18 type virus was 40%. The rate was significantly higher for those delivered vaginally compared with caesarean deliveries (51% vs. 27%).<sup>149</sup> A 30% transmission rate of the virus to the oropharynx of the neonates has been reported in another study; it also showed that the virus was cleared by five weeks.<sup>150</sup> Manns documented that only 3% of infants were seropositive to HPV-16 by 1–2 years.<sup>151</sup>

## CLINICAL COURSE DURING PREGNANCY

For reasons not fully known, genital warts frequently increase in number and size during pregnancy, sometimes filling the vagina or covering the perineum and making it difficult to perform vaginal delivery or episiotomy. Certainly, the vaginal mucus throughout pregnancy offers ideal moist conditions for viral growth. Accelerated viral replication with advancing pregnancy has been hypothesized to explain the growth of perineal lesions, progression of some to cervical neoplasm, and the increased detection of viral DNA from the cervix of pregnant women.<sup>152</sup> Because papilloma virus infection can be subclinical and multifocal, most women with vulvar lesions also have cervical infection, and vice versa.<sup>153</sup> Vulvar lesions often improve rapidly or disappear in the postpartum period, possibly related to the loss of either vascularity, excessive moisture or the alleged immunosuppression of pregnancy.

## SCREENING AND PREVENTION

The human papillomavirus (HPV) vaccine may prevent infection with certain serotypes of human papillomavirus associated with the development of cervical cancer, genital warts, and some other less common cancers.<sup>154,155</sup> Two HPV vaccines are currently in the market: Gardasil and Cervarix.<sup>156</sup> Both vaccines protect against two of the HPV types (HPV-16 and HPV-18) that can cause cervical cancer and some other genital cancers; Gardasil also protects against two of the HPV types that cause genital warts.<sup>154</sup>

Public health officials in Australia, Canada, Europe, and the US recommend vaccination of young 9–26 years women against HPV to prevent cervical cancer and genital warts

In the Gardasil clinical trials, 1115 pregnant women received the HPV vaccine. Overall, the proportions of pregnancies with an adverse outcome were comparable in subjects who received Gardasil and subjects who received placebo.<sup>157</sup> However, the clinical trials had a relatively small sample size. Currently the vaccine is not recommended for pregnant women.<sup>154–157</sup>

## TREATMENT

There are relatively few randomized controlled trials of the effectiveness of various treatment regimens for anogenital warts and there appear to be none conducted on pregnant women. Many treatment regimens that are effective in nonpregnant women are suitable for use in pregnancy, except cytotoxics like podophyllin, or podophylotoxin that should be avoided because of a theoretical risk of teratogenicity. The aim of the treatment is to destroy the wart tissue and, although most treatments are effective, this tissue destruction is not necessarily associated with the eradication of HPV. It has not been determined whether transmission to the neonate from the normal intact skin infected with HPV is less than from symptomatic warts. Effective treatments include cryotherapy, cauterization with trichloroacetic acid, excision, electrocautery, and laser therapy. Recurrences after therapy are common. During pregnancy,

the growth of anogenital warts can occasionally become very rapid and treatment may have to concentrate on a strategy of maintaining the status quo rather than the complete removal of the warts. Very rarely, if neglected, anogenital warts can become so large that they may obstruct vaginal delivery in which case a caesarean section is indicated.

## Granuloma Inguinale (Donovanosis)

Granuloma inguinale is a genital ulcerative disease caused by the intracellular gram-negative bacterium *Klebsiella granulomatis* (formerly known as *Calymmatobacterium granulomatis*). It is endemic in some tropical and developing areas, including India, Papua New Guinea, central Australia, and southern Africa. Clinically, the disease is commonly characterized as painless, progressive ulcerative lesions without regional lymphadenopathy. The lesions are highly vascular (i.e., beefy red appearance) and bleed easily on contact. However, the clinical presentation also can include hypertrophic, necrotic or sclerotic varieties. The causative organism is difficult to culture, and diagnosis requires visualization of dark-staining Donovan bodies on tissue crush preparation or biopsy.

## Clinical Course During Pregnancy

The lesions of donovanosis tend to proliferate or recur and show diminished response to standard antimicrobial therapy.<sup>158–161</sup> The cervical lesions may rapidly enlarge, extend to the pelvic structures, and disseminate resulting in fatal hemorrhage at the time of delivery.<sup>162,163</sup> This is due to increased vascularity of the lesions and the immunosuppressive effect of pregnancy.<sup>164</sup> Hypertrophic variant is more commonly seen in pregnancy.<sup>165</sup> However, in a recent study there was no difference in the type of lesions and response to therapy in patients with and without pregnancy.<sup>162</sup>

## Perinatal Transmission

This has been reported occasionally. The lesions reported in neonates and infants, probably due to vertical transmission in mothers with untreated donovanosis, include suppurative otitis media, cervical lymphadenopathy, and lesions on the umbilicus, labia, and penis.<sup>163–167</sup>

## Treatment

A limited number of studies on Donovanosis treatment have been published. Treatment halts progression of lesions, although prolonged therapy is usually required to permit granulation and re-epithelialization of the ulcers. Healing typically proceeds inward from the ulcers margins. Relapse can occur 6–18 months after apparently effective therapy. Several antimicrobial regimens have been effective, but a limited number of controlled trials have been published.<sup>168</sup> Doxycycline 100 mg orally twice a day for at least 3 weeks and until all lesions have healed completely is the recommended regimen.

## Alternative Regimens

Azithromycin 1 g orally once a week OR Ciprofloxacin 750 mg orally twice a day OR Erythromycin base 500 mg orally four times a day OR Trimethoprim-sulfamethoxazole one double-strength (160 mg/800 mg) tablet orally twice a day. All therapies should be continued at least 3 weeks or until all lesions have completely healed. Some specialists recommend the addition of an aminoglycoside (e.g., gentamicin 1 mg/kg IV every 8 hours) to these regimens if improvement is not evident within the first few days of therapy.

Pregnancy is a relative contraindication to the use of sulfonamides, doxycycline, and ciprofloxacin. Pregnant and lactating women should be treated with the erythromycin regimen and consideration should be given to the addition of a parenteral aminoglycoside (e.g., gentamicin). Azithromycin might prove useful for treating granuloma inguinale during pregnancy, but there are few published data.

## Conclusion

STIs are common infections of young people in the reproductive age group. During pregnancy these infections not only affect the maternal health but also have significant effect on their reproductive outcome (abortion, preterm birth, stillbirth congenital infection and postpartum infection, ectopic pregnancy, and infertility).

Women with STIs may not have symptoms and may not know the significance of their not very distressing symptoms during pregnancy. Screening all women during pregnancy at the first prenatal visit and repeat screening in 3rd trimester or at labor (for women not tested in prenatal time) provides a good opportunity to detect these infections and treat them during pregnancy.

Most of the recommended treatment regimens in pregnant women do not differ from those for the non pregnant women.

Pregnancy provides an excellent window of opportunity to obstetricians to screen the women and treat them with appropriate regimen in whom infection is diagnosed.

Obstetricians also have a good opportunity to counsel their women for preventive measures, like use of condoms and avoidance of high risk behavior. All these measures can go a long way to help the woman, her partner, the new born, and the society at large.

## Sexually Transmitted Infections in Neonates and Infants

P. Janet Say • Ravi Chandra Sharma

### Introduction

Sexually transmitted infections (STIs) in infants and newborns can follow vertical transmission during pregnancy or delivery, or rarely be acquired from external source, non-sexual contact post-delivery. *In utero* infections occur from placental spread, and these include syphilis or cytomegalovirus (CMV). Ascending infections causing chorioamnionitis may follow premature rupture of membranes (PROM). An infected birth canal during delivery is the source of other infections such as herpes simplex virus, HIV, Hepatitis B, human papilloma virus, gonorrhoea, and *Chlamydia trachomatis* (CT). Post-natal infections occur from breastfeeding (HIV) or may follow transmission from an exogenous source (Herpes simplex). The high incidence of STIs in the adult population in developing countries generally correlates with the high frequency of congenital syphilis and ophthalmia neonatorum (ON) reported from these countries.<sup>1</sup>

STI control is particularly compelling because of its reproductive sequelae, fetal wastage, prematurity, and other complications caused by STIs especially in the developing countries.

Neonatal infections are those defined as occurring in the first month of life. It is at this time, particularly in neonates of low birth weight, there will be diminished efficacy of immune function. Maximal maternal protective immunoglobulin crosses the placenta late in gestation and the amount will be limited depending on the degree of prematurity. Therefore the increased susceptibility of the premature neonate to all these infections can be easily understood.

### STIs in Newborns

Neonatal conjunctivitis or ON from gonorrhoea has been well documented since 1882 as a cause of blindness. This initiated successful use in some countries, of Crede ocular prophylaxis at birth. It is now known that conjunctivitis is often more commonly caused by CT and this does not respond to ocular prophylaxis with silver nitrate.<sup>2</sup> STIs in the neonate can include trichomoniasis, herpes simplex viruses 1 and 2, human papilloma virus, CMV, the hepatitis B, C, G virus as well as other bacterial

infections including *Streptococcus agalactiae* (Group B Strep). The latter is associated with bacterial vaginosis (BV), which along with mycoplasmas, (also part of the mixed bacterial flora of BV) have been shown to be associated with amnionitis and preterm delivery.<sup>3</sup> Of the commonly considered congenital infections, CMV, syphilis, and herpes simplex virus are the ones most commonly transmitted from the mother.

### GONORRHOEA

The incidence of gonorrhoea in pregnant women has varied from rare to 10%. The chief manifestation in the newborn is conjunctivitis. Other manifestations include meningitis (fatal fulminating meningitis with Waterhouse–Friderichsen syndrome and adrenal hemorrhage), endocarditis, gonococcal septicemia, arthritis, scalp abscess, vaginitis, urethritis, retinitis, proctitis, and funisitis (inflammation of the umbilical cord).<sup>4</sup>

### Epidemiology of Gonorrhoea

Information on the prevalence of gonococcal infection in the neonatal period is limited. The estimated incidence, 6.5 per 100,000 population, was reported from USA<sup>4</sup> in the 1980s. Gonococcal infection of the newborn occurs by vertical transmission from the infected mother during delivery. Contamination of the fetus may also occur *in utero* if there is early rupture of membranes and amnionitis.<sup>5</sup> Scalp abscesses following attachment of probes for fetal monitoring have been described.<sup>6</sup> The estimated rate of transmission from the infected mother to the newborn varies from 30% to 50%.<sup>7–9</sup>

Maternal gonococcal infection has been associated with a statistically greater occurrence of PROM, prolonged rupture of membranes, chorioamnionitis, and premature delivery.<sup>9</sup>

### Gonococcal Neonatal Conjunctivitis

Symptoms may present a few hours after birth in cases where there has been delay between the PROM and delivery up to 2–3 weeks.<sup>10</sup> The disease presents as a mucopurulent discharge

**Fig. 91.1:** Gonococcal ophthalmia neonatorum. *Courtesy:* Dr. BSN Reddy and Sujay Khandpur, New Delhi, India.

that literally pours out when the eyelids are separated, both eyes are nearly always affected (Fig. 91.1). The conjunctivae become intensely inflamed, bright red and swollen with marked chemosis. There is a dense infiltration of the bulbar conjunctiva initially that later becomes puckered and velvety with free discharge of pus, serum, and blood. A false membrane may form in a few cases resembling membranous conjunctivitis. Untreated cases develop corneal ulcers over an oval area just below the centre of the cornea. Rarely marginal ulcers may form followed by corneal perforation, iris prolapse, and extrusion of the lens.

Other complications include anterior synechiae, adherent leukoma, partial or total anterior staphyloma, anterior capsular cataract, and panophthalmitis. Macular fixation may be impaired causing nystagmus.

Local or systemic spread may occur resulting in oropharyngeal gonorrhoea in approximately 35% of cases, and meningitis and/or arthritis may develop. Joint manifestations usually appear in the third to fourth week and affect the knee, wrist, ankle, and elbow joints.<sup>11,12</sup>

### Laboratory Diagnosis

Culture is still more of a gold standard than polymerase chain reaction (PCR) and nucleic acid amplification tests (NAATs), which can give false positive results from commensal *Neisseria*.<sup>8</sup> Optimal isolation is by direct plating and immediate incubation in 5% CO<sub>2</sub>. Identification requires biochemical, serological, and enzyme substrate tests. The routine testing of sugar utilization is positive for glucose but not maltose, lactose or sucrose. *Neisseria meningitidis* has been described in neonatal conjunctivitis as well as other *Neisseria* species so that at least two types of identification methods are necessary.

**Nucleic Acid Amplification Tests for *N. Gonorrhoea*** These have been shown to be diagnostic. In the past, Amplicor (PCR) test gave false results with *Neisseria subflava* and *N. cinerea*.<sup>13</sup>

The CDC 2010 guideline includes the use of NAATs for the diagnosis of *N. gonorrhoeae* (NG) in children, using vaginal, urethral swabs, and urine. There is no approval as yet for the use of NAATs on throat or rectal swabs; cultures are indicated.

In a multicentric study to evaluate and compare nucleic acid amplification tests, with the standard culture technique, 485 female

children were investigated for infection. Prevalence of infection was 2.7% for chlamydia and 3.3% for *N. gonorrhoea*. Eight CT positive and four NG positive children with NAATs had culture negative results. The authors concluded that the Strand displacement amplification (SDA) and Transcription-mediated amplification (TMA) tests with confirmation by a different NAATs are adequate for use on urine samples as a new forensic standard for diagnosis of CT and NG in prepubertal girls suspected of sexual abuse. There has been no study in prepubertal boys. Other NAATs have been used regularly in the routine diagnosis of conjunctivitis. NAATs offer a clear advantage over culture in sensitivity and are less invasive, reducing patients' trauma and discomfort.<sup>14</sup>

### Treatment

Gonococcal ON is treated with Ceftriaxone 25–50 mg/kg IV or IM not exceeding 125 mg in a single dose. Alternative treatments for gonococcal infection in other sites can be cefotaxime 100 mg/kg IV or IM as a single dose. If there is disseminated gonococcal infection with arthritis or scalp abscess, ceftriaxone 25–50 mg/kg IV or IM is given daily for 7 days or cefotaxime 100–150 mg/kg/day IV or IM in three divided doses for 7 days. Meningitis may require treatment for 10–14 days and higher doses may be necessary.<sup>15</sup> Testing for CT should also be done concurrently. The parents of the child and/or other sex partners should be screened and appropriately treated. Occasionally, prophylactic treatment is indicated where mothers are known to have gonococcal infection and ceftriaxone can be used as above.

## Ophthalmia Neonatorum

A baby with purulent discharge from the eyes occurring within 21 days of birth is diagnosed to have ON.

In 1881, a Liverpool eye surgeon wrote that 60–75% of blindness in any large home for the blind was caused by ON. At the end of the 19th century in Europe the prevalence of ON among live births in maternity hospitals exceeded 10%. Corneal damage of the neonates developed in 20% and blindness in about 3% of the affected infants.<sup>16,17</sup> Blindness from ON is rare, especially in industrialized countries due to a low prevalence of STIs in pregnant women and prophylaxis at birth. Worldwide 1000–4000 new born babies become blind every year because of ON.<sup>18</sup>

In a recent study from Iran, 4021 neonates were examined for the presence of conjunctivitis and 198 (4.9%) were positive. Forty seven percent of the mothers of these babies had PROM and 11% had genitourinary infections. Most Common sexually transmissible causative organism was *N. gonorrhoeae* in 3% and *C. trachomatis* in 2%.<sup>19</sup> CT was detected by DFA staining in 31% of the 58 neonates with conjunctivitis in an Indian study.<sup>20</sup>

In 1998, the prevalence of gonococcal ON was reported as 0.04% in Belgium and Netherlands and 0.3 per 1000 live births in the USA.<sup>21</sup>

*Streptococcus pneumoniae*, *Haemophilus influenzae*, *Neisseria cinerea*, *Moraxella catarrhalis*, and viruses such as herpes simplex and adenovirus can also be co-infections.<sup>5,21</sup>

A study in Kenya in 1986 showed that of 42% of 67 babies born to infected mothers, who were not given prophylaxis against ON developed ON.<sup>22</sup>

### Prevention of Ophthalmia Neonatorum

Antenatal care should include the screening of at-risk women and their adequate treatment and that of the partner(s) predelivery. A precautionary second screening late in pregnancy is advisable in women who are at high risk. Rothenberg's review of 24 studies using silver nitrate topically (Crede's method) post-delivery prevented ON in 99.94% of cases.<sup>23</sup> Alternative prophylactic antibiotic regimens have been tried because of the risk of chemical conjunctivitis from silver nitrate and erythromycin has been found to be efficacious in several studies as an ophthalmic ointment.<sup>24,25</sup> According to CDC guidelines, povidone-iodine installation prophylaxis may not be successful in premature neonates with PROM and gonococcal amnionitis.<sup>15</sup>

In children born to untreated mothers, in areas where the prevalence of maternal gonococcal infection is greater than 1%, or where maternal screening is not undertaken, a two-stage prophylaxis, Crede's method, is followed. In the first step, the eyelids and eyelashes of the infant are wiped free of pus or organic matter as soon as the head is delivered and before the eyes are opened, in the second stage after the child is born, one or two drops, of 1% aqueous silver nitrate are instilled into each eye. Silver nitrate may not prevent the infection which is already established. Conjunctival irritation from the silver nitrate can occur from 6 to 24 hours after use but the reaction resolves by 24–48 hours.<sup>5</sup>

In the United States, 1% tetracycline or 0.5% erythromycin ophthalmic ointment are recommended (CDC). Topical tetracycline prophylaxis has some effect but little effect on subsequent development of chlamydial pneumonia.<sup>26</sup>

According to Hammerschlag, the most effective method of control of perinatal CT infection is screening and treatment of pregnant women.<sup>8</sup>

## CHLAMYDIAL INFECTIONS

### Conjunctivitis

Neonatal chlamydial conjunctivitis has been reported to occur in 52–75% of infants born to mothers with cervical chlamydial infection.<sup>27,28</sup> In Bell's study analysis of the incidence post-caesarean section showed 20% to be infected even with intact membranes. The incubation period can be from 3 days in premature infants, but mostly is between the 6th day up to 13 days. Fifty percent of infants also have nasopharyngeal infection, 20% of these may develop neonatal pneumonia and the middle ear, gut, and vagina may be infected.<sup>29</sup> The conjunctivae are injected. There will be a copious watery discharge which can be mucopurulent. There is papillary hyperplasia of the conjunctivae with swelling of the eyelids. Bilateral infections may be present in two-thirds of cases.<sup>30</sup> Occasionally, gonococcal neonatal conjunctivitis is

co-existent, but the relatively earlier incubation period should alert the clinician. The increased incidence of chlamydial neonatal conjunctivitis compared to gonorrhoea would indicate treatment for both. Most cases of chlamydial D-K infections are benign, some are even asymptomatic. But there are reports of micropannus formation and occasional scarring.<sup>31</sup>

### Chlamydial Pneumonia

Lower respiratory tract infection in the form of an atypical pneumonitis may follow in a 6th of babies born with conjunctivitis, particularly if systemic antibiotics are not used in treatment of the latter. Per nasal swab culture may confirm the diagnosis of nasopharyngeal infection, but often the infection is missed as this can present 3 weeks to 3 months post-delivery. Apnoeic attacks are frightening for the mother and the child may have a "staccato" cough. Patchy signs may be present on chest X-ray, and eosinophilia and increased immunoglobulins on blood testing. A positive chlamydia micro-immunofluorescence (MIF) test may be helpful with an IgM titer of 1:16 or more. It is not yet clear if *C. trachomatis* pneumonitis is associated with chronic lung disease.

Other infections with similar presentations include respiratory syncytial virus and *Mycoplasma pneumoniae*.<sup>32</sup> Infants with chlamydial pneumonia have also been described with middle ear infection, serous otitis media,<sup>33</sup> which may lead to middle ear infection in older children.<sup>13</sup>

### Laboratory Diagnosis

The Giemsa stain of a conjunctival scraping for the characteristic basophilic intracytoplasmic inclusions may be helpful. Culture on McCoy cells from conjunctival scrape swabs has been the mainstay or gold standard of diagnosis. CDC has approved the use of enzyme immunoassays and direct fluorescent antibody test in the past for the diagnosis of chlamydial conjunctivitis. Tests generally approved by CDC include PCR, SDA, and TMA NAATs (their use on pharyngeal and rectal swabs is still being assessed).

PCR for conjunctival swabs gave a sensitivity of 92.3% and specificity of 100%. Other NAATs have not been adequately tested from this site but are used.<sup>34</sup>

### Treatment of Chlamydial Infections

Systemic treatment for chlamydial ON should be offered in the form of oral erythromycin base or ethyl succinate for 14 days, topical therapy is not indicated. Erythromycin is given as four divided doses of 50 mg/kg/day orally. Up to 80% of infants respond but a second course of treatment sometimes has to be given. Mothers and their sexual partners should also be screened and appropriately treated. Similarly in cases of pneumonia, the treatment is for 14 days with erythromycin at 50 mg/kg/day divided into four doses. Again a further course of erythromycin may be indicated as 20% may not respond fully to the initial course.<sup>15,35</sup>

## Trichomonas Vaginalis

Risk of neonatal trichomoniasis is increased in children born with low birth weight, preterm delivery and PROM. This motile protozoan is transmitted through an infected birth canal. Carriage and/or infection are recorded post delivery up to the 19th day.

The vaginal epithelium of the infant is thought to be prone to the infection while maternal estrogen is present. Estrogen causes epithelial thickening, there is a lower vaginal pH and more glycogen, but this is transient. The infection may be asymptomatic or present with a purulent vaginal discharge, pyuria may be found and the respiratory tract may be involved. However, usually the infection is very transient and probably missed.

A study of 984 neonates included 333 swabbed and/or cultured for *Trichomonas*; 0.1% were diagnosed on microscopy, and 0.6% more were detected where culture was used.<sup>36</sup> Respiratory distress has been reported where *T. vaginalis* has been isolated from nasal secretions.<sup>37</sup> A 2 week old girl with herpes encephalitis and respiratory symptoms responded to Metronidazole after *T. vaginalis* was isolated from a nasopharyngeal wash. The organism was diagnosed by PCR, typical electron microscopy appearance, and on cloning was identified as *T. vaginalis* rather than *T. tenax*.<sup>38</sup>

## NEONATAL HERPES SIMPLEX VIRUS INFECTION

About 50–80% of neonatal herpes simplex virus (HSV) infections are caused by HSV 2.<sup>39</sup> HSV infection of the newborn can be acquired in three ways. Intrauterine infections (approximately 5%) can occur as a consequence of either transplacental or ascending infection. The most common mode of infection (80–90%) is by contact with infected maternal genital secretions during birth. The third method of infection is postnatally (10–15%).

The duration and quantity of viral shedding and time to healing in the mother varies with whether it is a primary infection or a non-primary first episode or recurrent (HSV1 and HSV2). These are the major factors that influence the frequency of transmission and perhaps the severity of neonatal infection. The mother's antibody status to HSV at delivery appears to be an additional factor that also influences the severity of infection as well as the likelihood of transmission.

The risk of acquiring neonatal HSV infection from a recurrent maternal infection is about 0.05% from women who are asymptomatic at vaginal delivery. However, if they have symptomatic clinical disease at delivery, the risk of transmission is 0.25–3%.<sup>40</sup> In a large study, HSV culture and serum samples were obtained at the time of delivery. HSV was isolated from the birth canal of 202 women and 5% of their babies had acquired infection.<sup>41</sup>

The risk of acquisition from primary HSV infection at delivery is up to 57%, while vertical transmission rates of 25% are found in those with a non-primary first episode (infection with one virus type in the presence of antibody to the other virus type). However, most infants with neonatal HSV are born to mothers

with no history of symptomatic genital herpes at term. These women shed the virus asymptomatically.<sup>41,42</sup>

More than 2% of women seroconvert to HSV 2 during pregnancy. Neonatal HSV infection rates were 54/100,000 live births in HSV seronegative women, 26 among women who were HSV -1 seropositive only and 22 among HSV-2 seropositive.

Caesarean section reduced the HSV transmission significantly. Other risk factors for neonatal HSV included first episode maternal infection, HSV isolation from cervix at the time of labor, invasive monitoring, delivery before 38 weeks, maternal age less than 21 years and PROM.<sup>40</sup> Kropp reports an increasing number of neonatal herpes infections from HSV 1.<sup>43</sup>

## Intrauterine HSV Infection

Transmission before the 20th week of pregnancy can cause abortion in up to 25% of cases. Signs at delivery may include growth retardation, chorioretinitis, microcephaly/anencephaly, and skin scarring. Few may just have skin or eye lesions and which usually follow PROM.<sup>44</sup>

## Perinatal HSV Infection

Babies may present up to 5 days of life with no defining symptoms. Between 5 and 21 days of life,<sup>43</sup> presenting symptoms include fever, lethargy with seizures and respiratory distress. Typical vesicular rash may only be present in 40% and many infants never show any presence of vesicles.<sup>45</sup> Higher mortality rates are seen in the premature, those with disseminated intravascular coagulation, seizures, and/or altered conscious state.<sup>44</sup>

Cutaneous involvement is seen as discreet, as well as clusters of vesicles, that usually erupt on an erythematous base and are 1–2 mm in size. These vesicles may progress to larger bullous lesions. Infections involving the eye may manifest as keratoconjunctivitis or later as chorioretinitis.

Differential diagnoses include varicella zoster, enterovirus disease, and disseminated CMV disease. Vesicular lesions can imitate those caused by *Listeria monocytogenes* and so can those caused by bullous impetigo, enteroviruses, and CMV. Consideration should also be given for toxoplasmosis, rubella, and syphilis.

Mortality rates are dependent on whether the disease is involving the skin and mucous membranes or the CNS or it is disseminated. Treated skin and mucous membrane disease may have no mortality and a normal outcome in 98%, whereas disseminated disease may have a mortality of 30% even with treatment.<sup>40,46</sup>

Disseminated disease occurs in 25% and CNS disease in the form of encephalitis may occur in up to a third of neonates. It seems that maternal placental antibodies may prevent disseminated disease but not the spread of virus to the brain.<sup>47</sup> CNS involvement may present at 10 days up to 4 weeks of age with fever, lethargy, and irritability, seizures, focal neurological signs, and a bulging fontanelle. CSF shows predominantly mononuclear cells and elevated proteins. Untreated the mortality rate may be 50% and

morbidity, despite high dose of acyclovir and particularly, with neurological complication is common.

Even those infants presenting with skin and mucous membrane disease may progress to dissemination and in one study 24% had HSV DNA in the CSF detected by PCR testing.<sup>48</sup> Bullous lesions may recur as they follow viremia, which can be reactivated later in infancy. If there are more than three recurrences in the first 6 months of life, poor neurological outcome may occur.<sup>49</sup>

## Management of Neonatal HSV Infection

Early institution of therapy with a high index of suspicion is essential as only 40% will have bullous lesions and the mother may have been asymptomatic.<sup>45</sup> Progressive abnormalities of liver function may occur along with hepatosplenomegaly and thrombocytopenia. After consideration of the diagnosis antiviral therapy should be given immediately.

## Diagnosis

Rapid and very sensitive and specific PCR testing of lesions as well as viral culture of the CSF may be diagnostic.<sup>48</sup> Also culture specimens are suitable from blood, throat, nasopharynx, conjunctivae, and rectum or urine.

## Treatment

Intravenous acyclovir 20 mg/kg every 8 hours<sup>49</sup> is given for 21 days in cases of disseminated infection.<sup>15</sup> Long-term suppressive treatment to prevent cutaneous recurrence (commonly HSV2) and CNS complications need further study before routine recommendations can be made.<sup>50</sup>

## HUMAN PAPILLOMA VIRUS (HPV)

Human papilloma virus genital types can be transmitted to the baby, mostly at birth through an infected birth canal. Maternal genital warts (usually non-oncogenic types 6 and 11) can increase in size and number during pregnancy and may be transmitted to the neonate. The vast majority of genital warts in pregnant women clear up post delivery.

HPV types 6 and 11 have been associated with laryngeal papillomatosis in children but this usually presents after 3 up to 4 years.<sup>51</sup> The incidence given is one case/3.5 million person-years and a prevalence of four cases per 100,000 children.<sup>52</sup> This serious complication particularly when recurrent is rare. HPV colonization in the neonate is transient in most cases.

Although HPV DNA has been found in amniotic fluid and in cord blood samples,<sup>52</sup> it is still unclear whether this route of transmission is significant. Jayasinghe has reported in a study of 574 women that 1.65% of newborns were HPV DNA positive at a mean of 65 hours after birth.<sup>53</sup> However, from the studies done it is clear that contamination rather than infection had occurred in most cases and even HPV 16 antibodies clear by 10 months.<sup>54</sup> Caesarean section is not indicated to prevent transmission of

HPV although occasionally genital warts may be so large vaginally as to be a risk of obstructive labor and recourse to caesarean delivery is thought necessary.<sup>55</sup>

## NEONATAL HEPATITIS

Neonatal hepatitis can be caused by Hepatitis B and C as well as other STIs particularly syphilis and CMV.

## Neonatal Hepatitis B

Most of HBV transmission occurs from asymptomatic carriers during labor and delivery. Although the exact mechanism is not known, it is presumed to result from exposure to maternal blood, genital secretions or both. Transmission is more common from women with the presence of HBeAg in their blood.

Twenty five percent of women with acute Hepatitis B during pregnancy may have a premature delivery, less commonly, an abortion or a still birth. The child may also present with failure to thrive, jaundice, and could proceed to liver failure if the mother has had acute Hepatitis B pre-delivery. If acute infection occurred in the last trimesters there is 70% risk of transmission to the baby. If acute Hepatitis B occurs in the first two trimester there is a 5% risk. If the mother is HBeAg positive the risk of infection from the mother to the child is up to 90% during delivery. If the mother has got HBcAb and is negative for HBeAg, the risk is much lower. Unfortunately, if infected the child is often asymptomatic and may develop chronic carriage in 90% of cases compared to adults, where only up to 10% of those infected, may go on to persistent carriage.

Perinatal transmission is the usual method of acquisition and policies of prevention of infection from mother to child have been in place for some years and have been assessed regarding efficacy. A 10 year neonatal Hepatitis B vaccination program in the Netherlands from 1982 to 1992 documented 705 infants from Hepatitis B antigen-positive mothers. Eight infants were born to 114 HBeAg positive mothers and became carriers within the first year of life with the protective efficacy rate (PER) of passive and active immunization at 12 months follow-up at 92%. The factor affecting the PER was the level of maternal HBV DNA. PER was 100% if maternal HBV DNA was less than 150 pg/ml and 68% for HBV DNA levels more than 150 pg/ml.<sup>56</sup> At 5 years follow-up significantly more infants had loss of sero protection who started active immunization at birth as compared to those starting at age of 3 months.

The clinical manifestations were reported in a study of mothers with acute Hepatitis B where HBsAg was detected in 17 out of 31 infants. Neonatal infection developed in one of 10 babies when maternal hepatitis occurred in the first two trimesters and in 16 of 21 babies when it occurred in the third trimester or within 2 months after delivery. Two of the 17 infected infants developed jaundice at 3 and 4 months of age and 13 infants who became infected showed no clinical signs of illness although they retained their antigen positivity for up to 39 months with raised liver enzymes (SGPT). Also liver biopsies on 10 infants between 3 and 27 months of age showed features of unresolved hepatitis.<sup>57</sup>

Prevention protocols for neonates usually consist of giving Hepatitis B immunoglobulin (HBIG) one dose of 0.5 ml intramuscularly within 12 hours of birth. At the same time, Hepatitis B vaccination is delivered in a different site intramuscularly and repeated at 1–2 months and at 6 months.

Hepatitis B can possibly be transmitted to breastfed infants from mothers who are chronic Hepatitis B carriers. However, in a study from Texas where HBV carriers were given HBV immunoprophylaxis and followed up for 15 months, none of 101 breastfed (mean length of breast feeding 4–9 months) infants but nine of the formula fed infants (3%) were positive for HBsAg.<sup>58</sup> It can be inferred that with appropriate immunoprophylaxis, breast feeding of infants by chronic HBV carriers poses no additional risk of transmission.

## Hepatitis C

Kumar et al. studied 830 pregnant women in an Indian antenatal clinic with testing for anti HCV with a third generation ELISA. Antibody-positive women were tested for HCV RNA and the mothers were evaluated for the presence of risk factors for HCV infection. 1.03% (84) women had HCV antibodies and 46 of these (54.8%) were positive for HCV RNA. There were no recorded risk factors for HCV positive status.<sup>59</sup> This infection varies in prevalence in different populations and in countries and in women with different risk factors, i.e. rates may be higher in IV drug using women.

Thomas et al. reviewed 976 infants from 28 studies followed up sufficiently for recalculation of transmission rates. Overall transmission rates were less than 10% in 8/12 studies of HIV-negative mothers, compared with 2/7 studies comprising at least 50% HIV-coinfected mothers. Nine studies measured maternal viremia levels, with only 2/30 transmitting mothers having <10(6) copies/ml of HCV RNA. Eight transmissions were identified overall from non-viremic mothers.<sup>60</sup> Majority of infections are probably acquired from infectious blood at delivery although the infant may not be viremic until several weeks afterwards. Current opinion does not support the use of caesarean section to prevent transmission.<sup>60,61</sup>

Antibody to HCV will be present in the infant at delivery which can be maternal. There is no indication for testing cord blood. Confirmation of infection should be done at 4–6 months by HCV RNA (HCV PCR) as well as liver function tests. Transplacental antibody can be present for more than 12 months but if there is positive HCV RNA, pediatric referral is indicated.<sup>62</sup> In the Hepatitis C/HIV co-infected mother, after the first trimester, antiretrovirals should be prescribed to reduce the transmission of both HIV and HCV. PROM is a risk for HCV transmission and the use of scalp electrodes or amniocentesis should be avoided. Unfortunately, unlike Hepatitis B there are no interventions that can limit perinatal transmission.<sup>63,64</sup>

Although Hepatitis C can be transmitted perinatally and is present in the breast milk, actual infection following transmission through breast milk has not been described.

## Hepatitis G (GB Virus Type C)

Mother to infant transmission of hepatitis G virus has been documented. In a study of 2046 women predelivery, 46 mothers (2.1%) were positive for hepatitis G RNA and 25 of their infants were followed up for 12 months. Thirteen infants (52%) were viremic and this continued to persist. In the 12 uninfected infants, the mothers had lower viral load copies per ml at the time of labor, inferring that high-titer maternal viremia and mode of delivery are closely associated with mother-to-infant transmission (two high-titer mothers had elective caesarean sections).<sup>65</sup>

Maternal-to-infant transmission of hepatitis G may occur in 75–80% of cases while the rate of HCV is much lower at 2.8–4.2%.<sup>66–68</sup> HGV does not seem to induce hepatitis in the children.<sup>68</sup>

## CYTOMEGALOVIRUS INFECTION (CMV)

Cytomegalovirus can be transmitted to the neonate *in utero* (up to 2.4%). Ten percent of these congenitally infected children may have symptomatic disease at delivery. Cytomegalic inclusion disease (CID) may follow primary infection of women usually during the first half of pregnancy. During delivery, 2–28% of positive mothers may be shedders from the cervix and 50% of the infants may be affected. Because of maternal antibodies, the infant may rarely have symptomatic disease.

Reactivation of CMV in breast milk is very common if milk whey is analyzed by PCR.<sup>69</sup> Ninety six percent of seropositive mothers in this study had viral DNA in breast milk at a median of 3.5 days postpartum and infectious virus at 10 days. The majority of infected infants are asymptomatic and this is possibly related to maternal antibody, but there is a risk of disease particularly pneumonia in preterm infants or infants treated with steroids. In this study, congenital disease was ruled out with 87% of deliveries by caesarean and negative PCR taken at birth. Pasteurization of breast milk may inactivate CMV.<sup>70</sup>

CMV can be transmitted to the neonate by transfusion of non-screened blood.<sup>71</sup> In most neonates, symptomatic disease occurs if the mother was seronegative. The incidence is 10–30%, particularly in preterm infants and it has been shown previously to be related to the number of donors and titer of CMV in donor blood.<sup>70</sup> Prognostic outcome may be related to neonatal blood viral loads.

## Asymptomatic Infection

Almost 90% of infants with congenital CMV infections are asymptomatic and their long-term outcome is good. However, 5–15% of them are at risk of developing developmental abnormalities including sensorineural hearing loss (CMV is the commonest cause of this acquired congenitally), microcephaly, motor deficits, mental retardation, chorioretinitis, and dental defects, which become apparent within the first 2 years of life.

## Symptomatic Infection

The incubation period varies from 4–12 weeks. A febrile pneumonitis can occur as well as hepatosplenomegaly,

neutropenia, lymphocytosis, and thrombocytopenia. At birth neurological involvement can be diagnosed by PCR testing of the CSF. Even with asymptomatic disease a positive result correlates with poor neurodevelopmental outcome.<sup>72</sup>

CMV can be transmitted from person to person through body fluids and can be found in blood, urine, semen, cervical secretions, saliva, breast milk and transplanted organs and as with all herpes viruses affecting mucous membranes it can be intermittently excreted.<sup>73</sup> Viruria ensures isolation/PCR positivity from urine. Saliva, white blood cells, CSF, stool, and biopsy specimens can be positive for the virus. Amniocentesis is valuable antenatally for diagnosing CMV using viral culture and PCR tests.

In a study to assess maternal risk factors in 175 mothers against controls, women with gonorrhoea, trichomoniasis or BV had an increased risk of intrauterine transmission of the CMV as did those who were primigravid. The risk was also increased in young unmarried and lower income mothers studied in a predominantly black, low-income population.<sup>74</sup>

## Treatment

Ganciclovir 8–12 mg/kg given in divided doses at 12 hourly intervals for 6 weeks has been used with variable effects as assessed at 6 months or more. Oral Valganciclovir given as a dose of 16 mg/kg provides similar efficacy. Both these drugs can lead to neutropenia in 38% of patients.<sup>70</sup> In Iran, prolonged courses of oral analogs of ganciclovir for children with symptomatic congenital CMV are offered.<sup>75</sup>

## Conclusion

Neonatal STIs can have severe acute and long-term complications. Their recognition requires a high index of suspicion and early diagnosis and treatment is essential. Their epidemiology reflects that of the local adult population. Preventive measures should therefore be primarily directed at limitation of adult STIs through education, readily accessible and acceptable sexual health services, maternal screening, and use of barrier contraceptive techniques in high-risk populations.

## Introduction

*“The child enters the world with an enormous syphilitic burden ... (it) is a saturated solution of syphilis ... organs and tissue ... are swarming with treponemata.”*<sup>1</sup>

Congenital (also called intrauterine or antenatal) syphilis (CS) occurs when a fetus is infected with *T. pallidum* while in utero and is currently a growing case of concern for public health, especially in the third world, with 3–15% of women in their reproductive years infected and places where up to 17% of pregnant women have a positive serology.<sup>2,3</sup> In spite of the shortage of formal or complete records, statistics by the WHO allow an estimation of a million pregnancies negatively affected by syphilis each year.<sup>3–5</sup> CS in sub-Saharan Africa accounts for 11% of the 4 million neonatal deaths worldwide.<sup>6,3</sup> Where syphilis is prevalent, it may cause up to half of all stillbirths.<sup>7</sup>

The typical victims are fetuses from young mothers without adequate antenatal care (or none at all). They will become infected up to 95% of the times because the treponemes will reach them transplacentally via the blood. This transfusion of infected blood from the mother results in secondary syphilis in the fetus.<sup>8</sup> Besides abortion, stillbirth, and perinatal death, syphilis in the mother can lead to newborns with hepatosplenomegaly or babies born with early or late stages of syphilis, which in two thirds of the cases may be asymptomatic at birth and develop later causing characteristic malformations in the teeth and skeleton.

## History

Sexually transmitted infections (STIs) have had a significant impact on individual and collective lives within society since early history. Such is the case of syphilis, which has caused real epidemics affecting large numbers of people in Europe, the Middle East, and in America with devastating consequences throughout history. In spite of the controversies surrounding the origin of syphilis, it was undoubtedly recognized in Europe by the end of the fifteenth century and it became a fast-growing multinational epidemic, where the sexual aspect was predominant and its clinical traits made it be known and feared.<sup>9</sup>

Syphilis in infants has been described since the late fifteenth century, almost in parallel to the great European pandemic, and was the only non-venereal form of transmission found in medical descriptions once the most virulent phase of the disease had passed.<sup>10</sup>

In 1529, a hereditary component was described by Paracelsus, who believed the contagion was transmitted from father to child during conception.<sup>11–13</sup> Niccolò Massa, in 1537, concluded that children who were infected but had not been breastfed had received the disease through their mother's infected blood.<sup>14</sup> Still in the sixteenth century, French physician A Ferrier saw infection during conception or through “vicious humors” from the pregnant mother.<sup>12,15</sup> Later, in the seventeenth century, the high rate of miscarriages, stillborns, and infant death was attributed to “plague, smallpox, and venereal disease,”<sup>16</sup> and by the end of the eighteenth century, in L'Hôpital des Vénériennes, in Paris, anti-syphilitic treatment was given to mothers, their newborns, and their nurses.<sup>17</sup>

The knowledge about syphilis in all its forms gained momentum after the 1850s, a time rich in discoveries on different fields in the natural sciences. The development of the ideas from the nineteenth century that affected the concepts about CS is outlined below. In the history of venereal disease, morality plays a very important part, since the great majority of the afflicted had acquired it through sin; i.e., illicit sexual activity. The origin of every infection could be traced back to prostitution and their promiscuity.<sup>18</sup> But in the case of CS, innocent babies were suffering (*“the monster is seen in its most cruel form where the innocent baby is its victim”*<sup>19</sup>). CS appears in plays and literature from the end of the nineteenth century and beginning of the twentieth. Famous cases are H Ibsen's play *Ghosts* (1881), the short story by Sir AC Doyle, *The Third Generation* (1894), and E Brieux's *Les Avariés*—named *Damaged Goods*, in English (1901). Ibsen's play is about the wife of an adulterous man who discovers that her son has CS; Doyle's story has an innocent young man committing suicide after finding out that he is infected because of the loose ways of his grandfather (assuming Lamarckian transmission that did not involve the mother) and therefore

should not marry. In *Les Avariés*, a less honorable man hides his disease from his bride and she gives birth to a syphilitic child. This play was called “*a powerful plea for light on this hidden danger that fathers and mothers, young men and young women, may know the terrible price that must be paid, not only by the generation that violates the law, but by the generations to come.*”<sup>20</sup>

Treponemes remained elusive until the twentieth century. Discovered in 1905 by zoologist Fritz Schaudinn and dermatologist Eric Hoffmann,<sup>21,22</sup> they were stained in 1906 with silver nitrate and demonstrated in tissues from infected newborns by C Levaditi.<sup>23</sup> Shortly afterwards, on the same year, AP von Wassermann, ALS Neisser, and C Bruck developed what became known as the Wassermann reaction, using treponemal antigens extracted initially from the liver of a dead syphilitic baby.<sup>21,24,25</sup> It was later shown that the test did not detect treponemes but the damage caused by them.<sup>25</sup> Nonetheless, it was fundamental to diagnose the presence of the pathogen and thus remission from the disease during or after treatment.<sup>21</sup>

## Changing Concepts about the Causes and Nature of Infantile Syphilis

Using the terminology of the nineteenth century, syphilis in the newborn could be “primitive,” if acquired from a lesion in the mother during birth or shortly after, and “hereditary,” if a parent (almost always the father<sup>26</sup>) was “tainted” with an active or latent syphilis during conception,<sup>27,28</sup> or if the pregnant mother passed it to the fetus through the blood.<sup>29,30</sup> For some, only the latter was considered “congenital,”<sup>31</sup> but for others, the father’s seed, the mother’s blood, and the nurse’s milk could all transmit “hereditary” syphilis.<sup>32</sup>

### TRANSMISSION THROUGH MILK

In 1499, G Torella noticed that infants would be infected by their nurses through their milk or lesions in the breasts or mouth.<sup>11,33</sup> A Paré, in the sixteenth century, tells about a wet nurse who was sent to prison to be lashed as a punishment for infecting a whole family with syphilis.<sup>34</sup> Much later, looking at the case, it could be hypothesized that the nurse was in fact a victim of the disease of the father of the family, whose child had CS and transmitted it to her when breastfeeding. These cases of acquired syphilis, abundant in the literature of the eighteenth and nineteenth centuries,<sup>35,27</sup> can be summarized by the words of a physician called B Mandeville in 1724: “Men give it to their wives, women to their husbands, or *perhaps* their children; they to their nurses, and the nurses again to other children...”<sup>29,33</sup> There were no doubts about children transmitting primary syphilis,<sup>11</sup> and to prevent wet nurses from being infected, artificial nipples of different materials (wood and cork or even silver) were used.<sup>36</sup> In fact, children from syphilitic parents were not supposed to be breastfed by a healthy nurse; the general recommendation since the second half of the nineteenth century was for the mother to feed the baby, because her latent syphilis conferred immunity.<sup>27,37</sup>

In the eighteenth century, the quality of breast milk was recognized as paramount for the child’s development, and if a

wet nurse had to be used, she was to be carefully selected—even her character, emotions, and mood would greatly affect the health of the child.<sup>38</sup> Again, moral played an important part because, mostly, wet nurses were women of low resources and very possibly “unclean,” with illegitimate children. If syphilis could actually be transmitted through milk was still debatable in the nineteenth century; some physicians were uncertain and expected further corroboration,<sup>11,39,40</sup> some considered the possibility,<sup>32,41</sup> while others focused in the arguments against it, which outweighed those in favor: no one could show evidence of an alteration of the milk due to disease and since it didn’t have “cellular elements,” it was incapable of carrying the poison.<sup>15,42</sup>

### INHERITANCE OF INFECTION

Already in 1558, Paracelsus wrote that the French plague was hereditary.<sup>12,15</sup> Two hundred years later, in pre-revolutionary France, CA Vandermonde advised great care when choosing one’s partner; looking for natural beauty and avoiding “weak” individuals would prevent the inheritance of acquired diseases like syphilis and scurvy. For him and others, who advocated “physical and moral hygiene,” decadent behavior had brought infant mortality and infertility.<sup>43</sup>

In his influential *Treatise on the Venereal Disease* (1786),<sup>42</sup> John Hunter had denied the possibility of hereditary syphilis; he thought that only primary syphilis was contagious, wrongly dominating the ideas about the transmission of the disease for a long time. But in the following century, frequent discussions arose among experts from different medical fields, with opposing or complementary points of view about the causes and different aspects particular to infantile syphilis.<sup>15</sup> There was just too much conflicting evidence and too many interrogants.

Mothers who were apparently healthy alternated stillbirths with diseased and healthy newborns, and women who were patently syphilitic could give birth to healthy children. Sometimes twins would manifest the disease (or not) in completely different ways.<sup>11,29</sup> These observations meant years of confusion as to the route of transmission. Scientific journals from the nineteenth century abound in reports by perplexed, caring physicians describing healthy (“*plump, handsome and interesting*”) women falling ill shortly after marrying men who had been treated years before and had no longer symptoms. The Medical Times and Gazette of London stated: “*The father has the most direct influence over both mother and child’s health and can be called the origin of infection; diseasing a woman and the offspring is sure sign of latent syphilis.*”<sup>31</sup>

Thus, if the father had syphilis during conception, his sperm introduced the poison and, by dividing in the womb, gave it to every single tissue of the fetus,<sup>44</sup> killing it sooner or later “*...the fecundated germ... is blighted from the first.*”<sup>45</sup>

If the father was already cured, he was not contagious; the mother became poisoned only through the poisoned blood of the fetus, in contact with the placental blood.<sup>11,45–47</sup> Virtuous,

innocent mothers were thus infected by their syphilitic fetuses, while unmarried women with “loose habits” were always seen as the sources of contagion. Innocent or not, if the mother was infected, the main mode of transmission of CS was undoubtedly through the blood. In any case, the disease was the same, coming from the mother or the father.<sup>26</sup> Trying to understand the nature of transmission, physicians carefully registered each case adding information about the source of the disease: “father alone, mother alone, both parents”.<sup>48</sup> To collect this kind of information was hard for general practitioners, since the usual way for them to find out that a pregnancy was endangered was to notice a pregnancy in the mother who took a syphilitic infant or child to the hospital; only through careful questioning a previous history of miscarriages and a possibly latent infection in the father would be known. One of the first such studies was by M. Kassowitz, who in 1875 presented statistics from 330 children (or fetuses) belonging to 119 family histories obtained after years of observation and careful notes.<sup>15</sup> Another study on families showed 66% of mortality and a majority of weak, stunted, infantile syphilitics among the survivors.<sup>49</sup>

## INFLUENCE OF PARENTS

In the second half of the nineteenth century, embryology was becoming a modern science, based on cytology. K von Bauer had discovered the mammalian ovum in 1827, but although the cell theory was also being born, it took almost thirty years for both it and the spermatozoon to have the status of “cells.”<sup>50</sup> In 1875, after decades of debate on the influence of male and female on conception, O Hertwig established that fertilization involved the conjugation of both parts in a single cell.<sup>51,52</sup> It was therefore proposed that transmission of the syphilitic poison to an unborn child could come from two sides: during conception, from the mother’s ovum or the father’s sperm cell, both equally capable of transmitting characteristics (proper inheritance), or by transplacental infection in utero, with the mother as sole agent.<sup>12,15</sup> It had been proposed that syphilis from the father affected mainly the fetus’ liver, and that from the mother, its lungs.<sup>15</sup>

As for the effects of infection of the mother over the development of the fetus, in 1853 P Ricord took Hunter’s *Treatise* and added a new section on infantile syphilis stressing that “*an infant is badly lodged and poorly nourished in the womb of an infected mother, apart from the influence of the virus.*”<sup>42</sup> Abortion, miscarriage or stillbirth could happen even if the fetus was not syphilitic, only due to the defective nutrition from a sick mother.<sup>15</sup>

The effects of syphilis had been carefully studied by the late nineteenth century and some laws formulated concerning pregnancy: 1) syphilis before conception is more prone to abortion than if acquired during pregnancy; 2) if contagion happens at the time of conception, the rule are abortion and stillbirth; 3) if the disease is acquired in late pregnancy, the chances of survival are much better.<sup>45</sup>

## A “SYPHILITIC YEAST”

An interesting debate among the members of the Pathological Society of London took place in several sessions from February to April of 1876, starting and concluding with lectures by J Hutchinson. Talks of a living form capable of multiplying and developing in blood and tissues, a “syphilitic yeast”, were without any doubt inspired by L Pasteur’s works on fermentation, which favored the germ theory of disease against that of spontaneous generation.<sup>53</sup>

G Mendel’s Laws of Heredity had been published in 1865, but remained obscure until 1902.<sup>54</sup> Their recognition, together with the identification of the etiologic agent of the disease and the means to demonstrate its presence, finally invalidated both the concept of hereditary transmission (“*a micro-organism can never be part of inheritance*”<sup>1</sup>), and that either parent could be the direct source of infection. After 1912, the term “hereditary” was dropped from the medical literature about syphilis, remaining only “congenital” and “infantile syphilis.”

## History of Prevention and Antenatal Treatment

The Vaugirard hospice, opened in 1780 in Paris and devoted to children affected by venereal disease, allowed for the closer observation of a larger number of cases.<sup>55</sup> The sight of those children who survived was pitiful, and their short lives served as a punishment for the sins of their parents and as warning against libertine ways. The risk of a weak generation was also evident if diseased persons were to procreate.<sup>33</sup>

A charity institution to treat venereal disease opened in 1747 in London, the Lock Hospital. Trying to change the concept of sinful women as bearers of evil, the benefactors beheld them as victims and acknowledged that many of them had been infected by vicious husbands, diseased parents or children who were perhaps not theirs and had contracted the disease from a nurse. Progressively, married women and their children were treated as innocent while others were clearly considered guilty of their misfortune.<sup>56</sup>

In 1852, syphilization as a preventive or curative therapy was officially condemned by the Paris Academy of Medicine after a report that considered it “monstrously unreasonable,”<sup>57</sup> but in 1856, Norwegian CW Boeck reported using it on infants with CS in Christiania (now Oslo); he later wrote “my experience of the treatment of hereditary syphilis justifies me in continuing to practice syphilization...”<sup>58</sup>

Preventive medicine, as early as possible, was proposed: a positive Wassermann reaction in a mother or her newborn (even if apparently healthy) would indicate the need for treatment; children from parents shown to be free of the infection for over two years would be tested periodically during the first 2 years of life.<sup>1</sup>

Proper and early treatment would even alleviate society from potential criminals, since their “extremely unstable nervous equilibrium” made congenital syphilitics more prone to be delinquent.<sup>1</sup> The availability and efficacy of treatment (Salvarsan)

made it evident that early diagnosis and proper surveillance of the pregnancy could prevent CS.

The spread of antenatal care to the general population as well as pathological research on expelled, “macerated” fetuses, in the look out for *Spirochaeta pallida*, was strongly advocated by practitioners before the 1920s,<sup>49,59</sup> when Dame Janet Campbell in the UK started a national system with regular visits and procedures.<sup>60</sup> In 1923, an editorial in *Nature* citing a report of the Committee of Inquiry on Venereal Disease, by the Ministry of Health, read: “*It seems within the bounds of possibility that inherited syphilis may cease to exist some day, so effective is the treatment of the syphilitic mother during pregnancy in securing a healthy baby...*” The author was referring to treatments that combined mercury and salvarsan.<sup>61</sup>

Penicillin was found to be effective in 1943; in spite of the idea that it could be abortive,<sup>62</sup> it was used in pregnant women and first reports of encouraging treatment of CS were also discussed in *Nature*.<sup>63</sup> It prevented transmission to the fetus and could also cure it. Moreover, relatively small doses were effective treating infants with CS.<sup>64,65</sup> Sure enough, besides providing treatment, combating promiscuity was also a public health measure needed for the prevention of CS.<sup>66</sup> Antenatal care and treatment to prevent as many children as possible from being born as “such ghastly incarnations of hopeless misery”<sup>49</sup> means also less fatalities among the unborn<sup>45,59</sup> and with it, much pain within families.<sup>16</sup> Somehow shockingly, these losses could be openly disregarded: “*If every product of conception of a syphilitic mother were to reach maturity, the world would much sooner become over-populated and unable to support its inhabitants than would otherwise be the case. From this point of view alone I would not strongly advocate the antenatal treatment of syphilis, but from the point of view of preventing the unnecessary suffering of congenitally syphilitic children, the unhappiness it causes to the parents of such children. I most emphatically recommend the treatment of the pregnant syphilitic mother, for the sake of her child and of her own future health.*”<sup>7</sup>

Altogether, the twentieth century brought development and improvements that were reflected in a wider use of antenatal care in the whole world.<sup>67</sup> For the twenty-first century, the prevention of mother-to-child transmission of syphilis through more access to maternal health services, and an established surveillance of pregnancies including new technologies as point-of-care diagnostics was set to achieve the goal of eliminating CS as a public health problem.<sup>68</sup>

## Epidemiology and Burden of Disease

In the public health arena, syphilis shows its most negative effect when observed from the maternal and child health side. In 1948, the United Nations signed the Universal Declaration of Human Rights committing all the signatory members to particularly protect the health of the mother and child (United Nations, 1948). More than 60 years have gone by and the progress in protecting the mother-child health has been irregular. Interventions aimed at improving food, immunization, and integral management of diseases have had

measurable and beneficial effects and have achieved improvements in child survival. However, in spite of the significant decrease in mortality of infants and children under 5 years of age, there are still countries where mortality of these groups remains high, particularly in the developing part of the world.

The World Health Organization (WHO) estimates 3.3 million stillborn and over 4 million children who die before reaching 28 days of life.<sup>67</sup> According to WHO, the main causes of mortality in children under five lie on neonatal-stage pathologies with neonatal infections and prematurity as the most frequent causes.<sup>67</sup> WHO also estimates around 2.1 million pregnant women with active syphilis per year. Syphilis might be responsible for at least 500,000 perinatal deaths per year in Sub-Saharan Africa alone.<sup>69</sup> CS represents an important cause of mortality in this age group and some reports state that it may be the cause of as high as 26% stillborns.<sup>70</sup>

## CASE DEFINITION FOR CONGENITAL SYPHILIS

The case definition of CS changed from the classic criteria established by Kauffman<sup>71</sup> to that suggested by the Centers for Disease Control (CDC) in 1989. The CDC criteria includes newborns with clinical evidence of active syphilis, as well as those who do not present any signs, but whose mother suffered from an untreated or inadequately treated syphilis (CDC, 1989).<sup>72</sup> Table 92.1 shows some differences between the Kauffman and the CDC criteria for the case definition of CS.

The use of the CDC criteria increased the sensitivity of CS case reports, although high-risk cases that may not be infected were also included. The effects of the change of the criteria on the surveillance of the incidence of CS may be observed in the

**Table 92.1:** Differences Between the Kauffman and the CDC Criteria for the Case Definition of Congenital Syphilis

Kauffman criteria	CDC criteria
<b>Definite</b> Detection of <i>T. pallidum</i> in dark field or histological samples	<b>Confirmed</b> Laboratory demonstration of <i>T. pallidum</i>
<b>Probable</b> Increase in VDRL titers over 3 months or serological test that do not seroconvert after 4 months One major criterium or two minor ones plus a positive syphilis serological test or FTA One major and one minor criteria	<b>Presumptive</b> Any child of a mother with untreated or inadequately treated syphilis Any child with a positive serological test plus: Clinical findings compatible with syphilis VDRL in CSF or CSF with >5 cells or >50 mg/dl proteins with no other cause Reactive IG test for syphilis
<b>*Possible</b> FTA reactive test without clinical signs	<b>Syphilitic stillborn</b> Fetal death of over 20 weeks or 500 g weight to a mother with untreated or inadequately treated syphilis

Major criteria: condyloma lata, osteochondritis, periostitis, and hemorrhagic rhinitis. Minor criteria: scars in the labia, mucocutaneous lesions, hepatomegaly, splenomegaly, lymphadenopathy, hemolytic anemia, and neurological signs.

statistics of countries, as happened in the United States, where an important increase in the number of cases was seen after the change in case definition criteria for CS.<sup>73</sup>

### CONGENITAL SYPHILIS ESTIMATES

The rate of CS is directly related to the rate of syphilis in women at a reproductive age. Seroprevalence during pregnancy is quite low in the developed world, ranging from 0.002 in Europe to 4.3 in some regions in the United States.<sup>74</sup> However, few of these infections lead to CS due to very efficient prenatal care. For instance, in the United States, 13.4 syphilis cases per 100,000 live newborn were reported in 2000,<sup>74</sup> whereas nine presumptive cases of CS were reported in the United Kingdom between 1994 and 1997.<sup>75</sup> In contrast, CS case rates dramatically increased in rural areas of Eastern Europe and Asia.<sup>76</sup> In Africa, a high prevalence of maternal syphilis is reported in a sustained manner (3–18%) in prenatal clinics and because of this, CS rates are higher than 1% in day care centers.<sup>77</sup>

In the Latin American and Caribbean region in 2004, according to the Pan-American Health Organization (PAHO), the national STI/HIV/AIDS programs reported estimated prevalence rates of 3.1% in pregnant women with syphilis in the region, ranging from 1.00% in Peru and 6.21% in Paraguay. According to these data, the incidence of CS ranges from 1.40/1000 live births in El Salvador to 12/1000 live births in Honduras, whereas in the United States it is 0.10 cases per 1000 live births.<sup>78</sup> A recent survey,<sup>79</sup> which included 19 Latin American states showed that the commitment to eliminate CS has been taken up by all the countries, but at least 12 out of the 19 have not reached the minimum acceptable figure proposed as a target by PAHO: 0.5/1000 live births. (Fig. 92.1) Bolivia, Paraguay, and Haiti are the countries

that must make a greater effort to reach the proposed goal. Some of these countries do not consider the reporting of CS to be compulsory, although this is absolutely essential if the elimination program is to make progress.<sup>80</sup>

Schmid using data from the literature has estimated annually around 2 million maternal syphilis cases and from 728,547 to 1,527,560 congenital syphilis cases in the world<sup>81</sup> (Table 92.2).

The World Health Organization (WHO) estimates that each year, maternal syphilis is responsible for 460,000 abortions or stillbirths, 270,000 congenital syphilis cases and the birth of 270,000 premature or low-weight babies.<sup>82</sup> Adverse results in pregnancy are 12 times higher in women with syphilis than in seronegative women.<sup>83</sup>

A recent systematic review including 10 studies of interventions to improve the outcomes of antenatal syphilis screening has shown that it could reduce the syphilis-attributable incidence of still birth and perinatal death by 50%.<sup>84</sup>

Several studies mention the frequency of adverse events in untreated maternal syphilis. Some of them are summarized in the Table 92.3. The fact is that these adverse events average 65% of the products of mothers with syphilis, which represent a substantial negative impact of maternal syphilis in perinatal morbidity.

The prevention of congenital syphilis is based on syphilis screening in pregnant women and timely treatment with penicillin of those who are infected. Penicillin is highly effective, safe and the only recommended treatment for all pregnant women with syphilis.<sup>85</sup>

**Table 92.2:** Global Estimates of Syphilis in Women and Adverse Pregnancy Outcome due to Syphilis

Proportion of seropositive women with:	Conservative model (Watson-Jones et al.)*	Mid-range model (Schulz et al.)†	Less conservative model (Global Burden of Disease, WHO, 2000)
a. Untreated syphilis	0.95 <sup>a</sup>	1.0	1.0
b. High serological titer (≥1:8)	0.73	–	–
c. Adverse pregnancy outcome due to syphilis	0.49	0.65	0.75
Global annual number of congenital syphilis cases <sup>b,c</sup>	713,600	1,365,000	1,575,000

a Modified from Watson-Jones' model to reflect the proportion of seropositive women who did not receive prior treatment.

b Calculated as: 2.1 million maternal cases x Ax BxC.

c Includes miscarriage/fetal loss, perinatal death, premature birth/low birth weight, and neonatal infection.

## Pathology

*Treponema pallidum* can initiate an active infection in the fetus at any time during pregnancy after breaching the protective barrier formed by the placental villi, the amniotic membrane, and the maternal mucosal surfaces, along with their secretions. In adult syphilis, lesions are characterized by a pronounced mononuclear infiltration<sup>86,87</sup> with lymphocytes, macrophages, variable numbers of plasma cells and occasional polymorphonuclear leukocytes. Studies of the cellular phenotypes of syphilitic skin lesions in non-pregnant adults report large numbers of CD4<sup>+</sup> and CD8<sup>+</sup> lymphocytes and CD14<sup>+</sup> macrophages.<sup>88,89</sup> Varying numbers of plasma cells are also identified, but B lymphocytes are rarely detected. Most of the CD4<sup>+</sup> cells present in secondary syphilitic skin lesions have histiocytic characteristics<sup>89,90</sup> whereas immunostaining for CD3 revealed that the lymphocytes were predominantly CD8<sup>+</sup> cytotoxic T cells. Van Voorhis et al.<sup>88</sup> reported a Th1-like cytokine pattern in primary and secondary lesions with activated lesional CD8<sup>+</sup> T cells.<sup>88</sup>

Overall in CS, the more severely the fetus is affected, the greater are the pathological changes in the placenta. Placental histopathology associated with CS shows non-specific changes, including villous immaturity, enlarged villi and deciduas, plasma cell infiltrates, and proliferation of perivascular fibroblasts and endothelial cells. Acute infiltrates with polymorphonuclears (PMNs), with and without necrosis, are frequent in severe infections and chorioamnionitis. Chronic mononuclear infiltrates are also described in CS.<sup>91–95</sup> Sheffield et al.<sup>96</sup> studied placental and umbilical cord histopathology in 67 cases of confirmed CS, and found that maternal syphilis induces similar histopathologic changes in placentas as seen in adult syphilis, and noted that decidual plasma cells and chronic villitis are common regardless of the severity of the infection in the fetus. This wide histopathologic spectrum may resemble the natural history of the disease and the pleomorphism of the clinical presentations of syphilis in non-pregnant adults.

A review of the pathology of the lesions associated with CS shows a clear similarity among them. Pathology studies suggest involvement of several organs, with an extensive inflammatory response. Manifestations partly reflect the immunological maturity of the fetus—an observation noted by Silverstein 48 years ago.<sup>97</sup> In general, it is only at 22 weeks that the fetus is able to consistently build an immunological response to infection.<sup>98</sup> The interleukins, interferon levels, and the tumor necrosis factor

are much lower in premature newborns than in children born to term. This is an important finding given the central role played by cytokines in the physiopathology of CS.

In the umbilical cord of infected infants, similar changes may be seen, although histologically normal umbilical cords have been described. Acute and chronic inflammation and necrosis in the umbilical artery, umbilical vein, and Wharton's jelly are described. Funisitis is now considered the histologic marker of a fetal systemic response to intrauterine infection. Changes in the umbilical cord are classified as mild funisitis, marked funisitis without necrosis, and necrotizing funisitis.<sup>99–102</sup> The presence of *T. pallidum* is strongly associated with marked inflammation and necrotizing funisitis, and necrotizing funisitis correlates with worst outcomes.<sup>92</sup> Guarner et al.<sup>97</sup> studied 66 umbilical cords from infants born to women with syphilis and found histological abnormalities in 42% (11% necrotizing funisitis, 4% marked funisitis with no necrosis, and 27% mild funisitis); 58% of the cases had normal histology.

The immunopathogenesis of CS is poorly understood, and there is a need to define the basic components of the immune response to *T. pallidum* as a first attempt to better understand the pathogenesis of this infection. Although the cellular components of infiltrates in the placenta, umbilical cord, and fetal tissues have been extensively described, detailed immunological studies of the cell phenotypes in these tissues in CS are lacking. Acute and chronic inflammation has been described in the infected fetus. The typical inflammatory response is mononuclear and consists of macrophages, plasma cells, and lymphocytes. PMNs are rarely present in large numbers, unless in response to tissue necrosis. Abscess-like necrosis can be present in a wide variety of tissues. Gummatous lesions are not frequent; however,<sup>103–105</sup> Sheffield et al. have reported that necrotizing funisitis, acute villitis, and villous enlargement are more common findings in live born infants with CS, compared to stillborn infants in whom fetal vasculopathy and erythroblastosis were more common.<sup>96</sup> CD68<sup>+</sup> macrophages with absence of CD3<sup>+</sup> lymphocytes as a constant pathologic feature in all tissues were identified in a newborn,<sup>97</sup> and in cases of chronic syphilitic villitis, macrophages and T-lymphocytes from maternal origin were the predominant inflammatory cells with higher numbers of CD8<sup>+</sup> T-lymphocytes than CD4<sup>+</sup> T-lymphocytes.<sup>101,106</sup>

Some of the pathologic changes found in different organs in fetuses infected with *T. pallidum* are described in Table 92.4.

**Table 92.4:** Common Pathological Findings by Organ in Fetuses Infected with *T. pallidum*

Organ	Characteristics
Placenta	Thinning of the placenta; villitis with endovascular and perivascular infiltration
Liver	Inflammation of the interstitial stroma and in the perivascular tissue.
Lungs	The “pneumonia alba” is the classic lesion. The lung is yellowish-white, firm and enlarged. There is an increased amount of connective tissue.
Gastrointestinal tract	Mucosal and submucosal inflammation and mononuclear infiltration
Pancreas	Perivascular inflammatory infiltrate
Kidneys	Secondary damage by immune complex storage (similar to glomerulonephritis in adults), perivascular inflammatory infiltrate involving the interstitial tissue
Central nervous system	Involvement of the meninges, with thinning of the basilar meninges and endoarteritis. Neuronal damage dependent upon the intense involvement of blood vessels
Osseous system	May present with osteochondritis, periostitis, and osteomyelitis. The basic process of bone damage is based on the failure of the cartilage to become bone. These findings may reflect non-specific trophic changes resulting more from the direct <i>T. pallidum</i> effect from the severe generalized infection. This possibility is supported by the evidence that lesions may be cured without specific treatment.

## Clinical Features

In order to gain a better understanding of the various clinical forms of CS, ranging from fetal death to absence of symptoms in neonates, one must first understand some of the factors influencing the presence or absence of clinical forms. Fetal infection is the result of hematogenous spread of treponemes from an infected mother to the fetus. This transmission may also take place upon delivery as a result of direct contact between the newborn and the infectious genital lesions of the mother. Hematogenous spread relies on the appearance of circulating treponemes in the mother's blood. High concentration of treponemes are present in the early stages of syphilis, thus the probability of infection to the fetus in early stage maternal syphilis is close to 100%. After secondary syphilis, the probability of treponemes in blood decreases with time, thus reducing the possibility of transmission to the child when the mother's disease is in these stages.<sup>107</sup> Although the probability of transmission to the fetus may be as high as 70%, 4 years after the mother contracted the disease,<sup>108</sup> most neonates born to mothers with late stage latent syphilis are not infected.<sup>109</sup> The main factors that determine the probability of fetal transmission are the disease stage of the mother and the duration of the exposure in uterus.

In the past it was believed that the *T. pallidum* could not penetrate the placenta until after the 20th week of pregnancy. Investigators believed that the Langhan cell layer of the cytotrophoblast was an efficient placental barrier against infection during the first weeks. This theory, however, was discontinued once it was found that the Langhan cells layer was present throughout the pregnancy<sup>110</sup> and was found in women who transmitted the infection to their fetuses. Additionally, in 1974, Harter Benirschke tested fetal tissue from spontaneous abortions of women with syphilis, identifying treponemes in abortions after 9 and 10 week pregnancies.<sup>111</sup> On the other hand, Nathan et al.,<sup>112</sup> performed amniocentesis in 11 pregnant women with untreated syphilis between weeks 15 and 19 of their pregnancies (median 16.8 weeks). They used the rabbit infectivity test, identifying *T. pallidum* in the amniotic fluid of four of these eleven women. The study, however, failed to explain the mechanism by which *T. pallidum* entered the amniotic fluid and whether the fetus became infected by *T. pallidum* entering the placenta directly or by amniotic fluid intake or by an active mechanism of the fetus.

## Clinical Presentation of Congenital Syphilis

CS may cause fetal death, (presented as spontaneous abortion) generally after the first trimester of pregnancy,<sup>113</sup> stillborns; or may result in delivery of a premature newborn with evident signs of infection, or one who is completely asymptomatic.<sup>114</sup> Presentation of CS may be clinically similar to that observed after infection by cytomegalovirus, toxoplasma or rubella.<sup>115</sup> The clinical manifestations of CS can be classified into early and late stage manifestations. The early stage manifestations appear in the first 2 years of life.

### EARLY CONGENITAL SYPHILIS

When the fetus becomes infected, all the involved organs are affected due to dissemination of the treponemes. Hepatitis occurs as the earliest manifestation and may be diagnosed by finding increased transaminases in the fetal blood. Anemia and thrombocytopenia occur later and become evident through fetal hydrops or diffuse edema due to cardiac insufficiency, a negative Coombs result can help in the diagnosis.<sup>116</sup> Delay of intrauterine growth may also occur.

*Hepatomegaly* is the most frequent sign of early syphilis. Liver tests may be normal but jaundice caused by syphilitic hepatitis may develop with increased transaminases and alkaline phosphatase. Direct bilirubin may increase due to cholestasis. Prothrombin time could be increased.<sup>117</sup>

*Mucocutaneous manifestations* are observed in 70% of infected babies, at birth or develop during the first weeks of life. All mucocutaneous lesions have a large load of treponemes and are highly infectious.

Cutaneous manifestations include:

- Skin rash with bullae and desquamation in palms/soles (pemphigus syphiliticus): This is the most typical symptom. Tense

**Fig. 92.2:** Visceromegaly in a premature newborn with congenital syphilis. (Department of Neonatology, Instituto Materno Perinatal, Lima Perú. Courtesy of C. Velásquez).

vesicobullous lesions on palms and soles can be observed, with turbid and greenish content (Fig. 92.2). The vesicles break easily and leave the dermis unprotected. De-scaling occurs between the first and third week.

- Maculo-papular syphilides: occur on limbs and periorificial areas. The lesions are initially pink and evolve slowly and leave pigmentation (coffee and milk-colored spots). They resemble secondary syphilitic lesions in adults.
- Condylomata lata: may occur in mucous membranes or on the skin of areas affected by humidity or friction.
- Petechiae, in cases of severe thrombocytopenia.
- Anterior alopecia.
- Syphilitic paronychia (generally not involving the thumb).

The Syphilitic rhinitis or snuffles is a very common finding. A mucohemorrhagic secretion, as well as ulcerations on the upper lip and nasal vestibule are observed. It occurs in the first week of life. Even after treatment, these lesions may lead to permanent nasal deformities as sequelae.

Involvement of bones occurs in 60–80% cases of untreated CS, it is usually multiple and symmetrical, and resolves spontaneously within the first 6 months of life.

- Periostitis and cortical demineralization in the areas of long bone metaphysis and diaphysis (Fig. 92.3).
- Osteochondritis presenting in joints, mainly the knees, ankles, wrists, and elbows.
- Parrot pseudoparalysis: due to the pain by bone involvement the infected child will not move the affected limb.
- Wimberger sign caused by demineralization or destruction of the upper part of the metaphysis of the tibia which can be observed in x-rays.

\*c+

\*d+

**Fig. 92.3:** (a and b) Typical bullae and desquamation in palms and soles (pemphigus syphiliticus) of congenital syphilis. (Department of Neonatology, Instituto Materno Perinatal, Lima Perú. Courtesy of C. Velásquez)

Neurosyphilis can develop, frequently asymptomatic during the untreated neonatal period. The classical findings in the CSF in neurosyphilis are: a white blood count higher than  $25/\text{mm}^3$  (larger than  $200$  mononuclear cells/ $\text{mm}^3$ ), a protein count higher than  $150 \text{ mg/dl}$  ( $170 \text{ mg/dl}$  in premature babies), and a reactive VDRL.<sup>118</sup> Although sometimes, CSF results may be negative in spite of the neurological involvement, most of the CSF results are positive in symptomatic children and in 8% asymptomatic children. There are two forms of neurosyphilis:

- Acute syphilitic leptomeningitis is generally evident in the first months of life, with suggestive signs, such as those of acute bacterial meningitis (vomiting, enlarged fontanela, suture separation, increased cranial circumference). CSF results suggest an aseptic process. There is generally a good response to antibiotic treatment.<sup>119</sup>

**Fig. 92.4:** Syphilitic pneumonia (pneumonia alba) and visceromegaly in a case of congenital syphilis. (Departament of Neonatology, Instituto Materno Perinatal. Lima Perú. Courtesy of C. Velásquez).

- Chronic meningovascular neurosyphilis generally occurs at the end of the first year of life, with signs of progressive hydrocephalus, paralysis of the cranial nerve, and regression of neuro-development. Seizures and cerebral infarction may occur in 2-year old children due to syphilitic endarteritis.

Other systemic abnormalities seen in CS include:

- Splenomegaly (Fig. 92.4) and periesplenitis.
- Corioretinitis with a tendency to congenital glaucoma and uveitis.
- Luetic glomerulopathy which is more likely of late occurrence since it is immunologically mediated (antigen–antibody deposit over the epithelial surface of the glomerulo basal membrane). Clinical manifestations are those of a nephritic syndrome or nephritis.
- Anemia, thrombocytopenia, leucopenia, and leucocytosis occur with relative frequency. Hemolytic anemia may persist after several weeks of effective treatment.
- Syphilitic aortitis (generally asymptomatic).
- Pneumonia alba (Fig. 92.5), named after the white color of the lungs due to fibrosing pneumonitis, which looks like a diffuse lung infiltrate in x-rays.
- Other findings include failure to thrive, pancreatitis, myocarditis, ileitis, gastrointestinal fibrosis, intestinal mass, and pituitary gumma.

The classic triad for early CS includes skin rash in palms/soles, snuffles, and hepatosplenomegaly.

**Fig. 92.5:** Femur with signs of epiphysitis and demineralization in a case of congenital syphilis. Departament of Neonatology, Instituto Materno Perinatal. Lima Perú. (Courtesy of C. Velásquez).

### LATE CONGENITAL SYPHILIS

The treatment for CS has contributed greatly to reducing the signs of late CS. When the infection is not diagnosed or treated during the neonatal period, 40% of the untreated children show manifestations of the destruction caused by the primary lesions and thus, these lesions will not be reversed by antibiotic treatment. The following are characteristic lesions associated to late CS:

- Saddle nose, due to the destruction of the bone cartilage.
- Olympic forehead, due to prolonged periostitis on the frontal bones.
- Higoumenakis signs due to thinning of the sterno-clavicular area of the sternum.
- Tibial thickening (sabre shin): hunching or bending the anterior curve of half of the tibia due to periostitis.
- Clutton joints, which are symmetrical, painless swelling of knees or elbows, usually after a trauma. Mobility is preserved and it is thought to be associated to perisynovitis which can resolve spontaneously.
- Perforation of the hard palate.
- Hutchinson teeth due to syphilitic vasculitis, occurring since birth, harming the adequate development of the teeth (clam-like, incisors with central excavation). Another sign is mulberry molars (first multicuspid molars).
- Deafness due to affection of the 8th nerve, occurs in approximately 3% of untreated cases, and often starts with the loss of high frequency hearing around 8–10 years of age
- Interstitial keratitis (normally between 5 and 20 years of age), secondary glaucoma or corneal scarring.
- Optic atrophy due to early retinal damage or hydrocephaly.
- Rhagades, cracks on the skin, which has lost elasticity. They are especially frequent around the mouth, anus or genitals, and derive from mucocutaneous damage at birth.

The Hutchinson teeth, interstitial keratitis, and deafness make up the classic Hutchinson triad which is typical of late CS.

### Laboratory Diagnosis

The diagnosis of CS is not an easy task. A combination of both clinical and laboratory approaches is frequently used. Overall,

all syphilis diagnostic laboratory tests fall into two categories: (i) indirect non-specific and specific serological tests and (ii) direct detection of whole organisms or their components. The currently available diagnostic procedures have limitations, and the sensitivity and specificity vary according to the specific method and the stage of the disease. Direct detection tests for whole organisms or their components include dark-field microscopy, rabbit infectivity test (RIT), direct fluorescent-antibody test and nucleic acid amplification. The diagnosis of CS is further complicated, especially in the asymptomatic newborn, by the fact that *T. pallidum* cannot be isolated in vitro and maternal antibodies cross the placenta. RIT is still considered the “gold standard” and is highly sensitive. However, it is most commonly used in research settings and is impractical and expensive as a routine diagnostic procedure.

Excellent guidelines and algorithms for the interpretation of syphilis serological testing of mother and infants, and treatment recommendation are widely available in the literature.<sup>120</sup> Here, we want to emphasize key issues rather than provide a lengthy description of diagnostic aspects that experts agree are relatively standard in the diagnosis of CS. Because clinical findings may not be characteristic of syphilis in the baby, confirmation of a case of CS requires demonstration of the syphilis spirochete in tissues or body fluids samples by microscopy, of anti-*T. pallidum* IgM antibodies, or by DNA or RNA amplification. The low sensitivity and the technical requirements of traditional methods explain the low percentage of confirmed cases of infected newborns. The addition of nucleic acid amplification promises, however, to increase the number of cases detected.

In settings with limited resources, a presumptive case of CS (lack of a definitive demonstration of the organism) is frequently the basis for treatment of newborns. Ideally, when diagnostic capabilities are available the “standard” diagnostic approach is: (i) to confirm infection of the mother with a specific test; (ii) to determine whether the mother was adequately treated; and (iii) to determine clinical or laboratory evidence infection in the fetus.<sup>121–125</sup> With limited resources, the presumption of transmission to the fetus is raised by a positive serology of the mother with no antenatal care or inadequately treated maternal syphilis. In this context, treatment of CS is recommended based upon a maternal positive non-specific treponemal test at pregnancy or delivery in combination or not with clinical symptoms of the newborn.<sup>126,127</sup> In health facilities with more technological resources, the presumptive diagnosis of CS is further supported by histopathological changes in placenta, umbilical cord, and fetus. Overall, in absence of direct demonstration of the syphilis spirochete in fluids or tissues, histopathological examination supports the diagnosis of transmission of *T. pallidum* from the mother to the fetus.

While serology is a cornerstone in the diagnosis of adult syphilis, standard serologic tests have low sensitivity in CS<sup>128–131</sup> and, when positive, they reflect the passive transfer of IgG antibodies to the fetus, which usually become undetectable in the infant after 12–18 months.<sup>132</sup> Because maternal IgM does not

cross the placenta, a positive specific anti-*T. pallidum* IgM test is diagnostic of CS. Measurement of total IgM in the newborn and FTA-ABS IgM test have proven to have low sensitivity and specificity.<sup>133–138</sup> An improved version of the FTA-ABS test (19S FTA-ABS IgM) was later developed in which IgM antibodies are purified over a HPLC column.<sup>139</sup> Both the 19S FTA-ABS IgM as well as a commercial capture-IgM versions show, however, poor sensitivity.<sup>140</sup> Other methods such as immunoblot analysis using either total *T. pallidum* lysates or recombinants have been developed,<sup>141–143</sup> but they are also technically demanding and are primarily used in research facilities.

The poor sensitivity of microscopy, serology or histopathology for the demonstration of *T. pallidum* has prompted the search for alternative more sensitive ways for identifying the syphilis spirochete in the newborn. End-point (conventional) nucleic acid amplification and real-time DNA and reverse transcriptase PCR (RT-PCR) have been developed over the years and are being applied for the diagnosis of syphilis including congenital infections. Such methods include single target and multiplex PCR. Several conventional DNA PCR techniques that target four single-copy genes have been described for the detection of *T. pallidum*.<sup>141–148</sup> The *T. pallidum*-specific PCR assays have been used with a wide range of samples, among others, intraocular specimens, testicular tissue, genital ulcers, blood, brain tissue, CSF, amniotic fluid, placenta, umbilical cord, fetal tissue, and serum samples.<sup>149–162</sup> Initial studies in CS showed good correlation of DNA PCR with RIT and IgM measurements.<sup>142,151</sup> In addition to end-point PCR assays, real-time PCR methods have been more recently developed<sup>163–167</sup> with very high reported sensitivities and specificities when compared to conventional serologic tests to diagnose early syphilis infection in adults. Although very promising, their usefulness, specificities, sensitivities, and positive predictive values in CS are yet to be determined.

Rapid, on-site diagnosis of maternal syphilis is an emerging field in the prevention and treatment of CS. Most pregnant women in countries with limited resources receive inadequate syphilis testing, mainly because of lack of on-site testing and the need to return to the health facility for follow up. The World Health Organization is actively promoting the use of rapid syphilis tests (RST) in resource-poor countries.<sup>168</sup> A rapid test is a simple point-of-care test that can be used in all health care settings to allow immediate treatment. Although RPR testing can be considered a rapid test, there are clear advantages of RST using *T. pallidum*-specific recombinant antigens. RSTs require minimal training, no refrigeration and no laboratory, are easy to administer, can be transported and stored below 30°C, and can be used with whole blood, serum or plasma with no prozone effect. In field settings, maternal syphilis can be diagnosed and treated at the point-of-care avoiding adverse outcomes due to delayed treatment.<sup>169–171</sup> Numerous studies show the usefulness of rapid tests<sup>172–183</sup> in the rapid identification and treatment of infected patients. Sabido et al.<sup>184</sup> demonstrated that the average total time spent by patients in a rural health facility for clinical interview, sample processing, RST results and treatment was 88.9 minutes.

Despite the concern of overtreatment, RST has the potential of diminishing adverse outcomes as well as improve cost-benefit issues in maternal and CS.

## Treatment

Benzathine penicillin G (BPG) remains the pharmacological treatment of choice for both acquired and CS, due to the relatively low serum concentration of drug (0.018 mcg/ml)<sup>185–187</sup> necessary to kill *T. pallidum*. Treatment with BPG has been shown to prevent both transplacental passage of *T. pallidum* and also to treat infection after it has occurred. In their study, Alexander et al.<sup>189</sup> followed a cohort of 340 woman treated for syphilis antepartum with a dose of 2.4 million units (MU) of BPG and reported that congenital transmission was prevented in 98% of patients, regardless the stage of syphilis, and in 95% and 98% of women with secondary and early latent infection, respectively. Treatment with BPG is also favored over erythromycin and azithromycin, in that penicillin resistance has never been reported in *T. pallidum*; on the contrary, infection with macrolide-resistant *T. pallidum* strains has been reported.<sup>190</sup> Although penicillin-binding proteins have been described and characterized in *T. pallidum*, these proteins are more likely involved in the synthesis and assembly of the bacterial cell wall rather for penicillin binding.<sup>191</sup>

## TREATMENT FOR MATERNAL SYPHILIS

Pregnant women with a reactive serologic test for syphilis should be treated with the BPG according to the stage of syphilis. (Table 92.5).<sup>188,189</sup> Since maternal syphilis is usually detected through a screening test during pregnancy, most of these women will be considered early latent or may be late latent syphilis. So national recommendations for their management suggest the use of BPG 2.4 MU IM as a single dose or three doses (one weekly) plus the treatment of the partner (US Preventive Services Task Force 2009). Since syphilis is a risk factor for both acquisition and transmission of HIV,<sup>192</sup> the patient should also be advised

**Table 92.5:** Treatment Guidelines for Acquired Syphilis during Pregnancy\*

Stage of infection	Regimen
Primary Secondary Early latent (≤1 yr)	Benzathine penicillin G, 2.4 million units (mU) total, administered intramuscularly (IM) in a single dose
Late latent (≥1 yr) Late syphilis of unknown duration	Benzathine penicillin G, 7.2 mU total, administered as three doses of 2.4 million units IM each at 1 week intervals
Neurosyphilis	Aqueous crystalline penicillin G, 18–24 mU/day, administered as 3–4 mU intravenously (IV) every 4 hours or continuous infusion, for 10–14 days. Alternatively, procaine penicillin G, 2.4 mU IM once daily and probenecid, 500 mg orally four times a day, both for 10–14 days can be used.

\*Source: CDC. Sexually Transmitted Diseases Treatment Guidelines, 2010

to undergo HIV antibody testing at the moment of diagnosis of syphilis infection. Although literature refers that approximately 10% of pregnant women with syphilis report a history of penicillin intolerance,<sup>193</sup> there is very little evidence of the harm of penicillin treatment, manifesting as severe allergic reactions.<sup>194</sup> Only one study<sup>195</sup> published recently provides information on serious adverse events of penicillin treatment, though this is based on a large US insurance claims database, and includes men (35%) and women (53%) and information specifically of pregnancy was not available. The incidence of anaphylaxis after penicillin was reported to be 0.1/10,000 doses; adverse effect of drug, 2.1/10,000 doses; allergy, 2.4/10,000 doses; and any allergic reaction, 4.7/10,000 doses. One limitation is that the penicillin was given orally, while the treatment for pregnant women is IM.

As shown by Wendel et al.,<sup>193</sup> skin testing, when possible, might be an effective way to assess penicillin allergy, and should be performed to prevent any risk of drug-induced anaphylaxis during treatment. In case of positive skin test, oral penicillin desensitization (procedure is described in Table 92.6) can temporarily induce tolerance to the drug in the patient before parenteral penicillin is administered. Desensitization to penicillin before treatment is currently preferred to alternative pharmacological treatments.

**Table 92.6:** Oral Desensitization Protocol for Patients with Skin Test-Assessed -Lactam Antibiotic Allergy\*

Step†	Amount of β-Lactam antibiotic (Units/mL) ‡	mL	Units	Cumulative dose (Units)
1	1000	0.1	100	100
2	1000	0.2	200	300
3	1000	0.4	400	700
4	1000	0.8	800	1500
5	1000	1.6	1600	3100
6	1000	3.2	3200	6300
7	1000	6.4	6400	12,700
8	10,000	1.2	12,000	24,700
9	10,000	2.4	24,000	48,700
10	10,000	4.8	48,000	96,700
11	80,000	1.0	80,000	176,700
12	80,000	2.0	160,000	336,700
13	80,000	4.0	320,000	656,700
14	80,000	8.0	640,000	1,296,700
15	After 30 minutes from the last dose, administer 800,000 U of the same agent IV.

†Interval between doses: 15 minutes; elapsed time: 3 hours and 45 minutes; and cumulative dose: 1.3 million units.

‡The specific amount of drug was diluted in approximately 30 mL of water and then administered orally.

**Table 92.7:** Evaluation and Treatment of Infants for Congenital Syphilis\*

The following scenarios describe the evaluation and treatment of infants for congenital syphilis:

**SCENARIO 1.** Infants with proven or highly probable disease and an abnormal physical examination that is consistent with congenital syphilis, a serum quantitative non-treponemal serologic titer that is four-fold higher than the mother's titer<sup>†</sup>, or a positive darkfield or fluorescent antibody test of body fluid(s).

**Recommended Evaluation**

CSF analysis for VDRL, cell count, and protein.<sup>‡</sup>

Complete blood count (CBC) and differential and platelet count.

Other tests as clinically indicated (e.g., long-bone radiographs, chest radiograph, liver-function tests, cranial ultrasound, ophthalmologic examination, and auditory brainstem response).

**Recommended Regimens**

Aqueous crystalline penicillin G, 100,000–150,000 units/kg/day, administered as 50,000 units/kg/dose IV every 12 hours during the first 7 days of life and every 8 hours thereafter for a total of 10 days. Alternatively, procaine penicillin G, 50,000 units/kg/dose IM in a single daily dose for 10 days.

If >1 day of therapy is missed, the entire course should be restarted. Data are insufficient regarding the use of other antimicrobial agents (e.g., ampicillin). When possible, a full 10-day course of penicillin is preferred, even if ampicillin was initially provided for possible sepsis. The use of agents other than penicillin requires close serologic follow-up to assess adequacy of therapy. In all other situations, the maternal history of infection with *T. pallidum* and treatment for syphilis must be considered when evaluating and treating the infant.

**SCENARIO 2.** Infants who have a normal physical examination and a serum quantitative non-treponemal serologic titer the same or less than four-fold the maternal titer and the mother was not treated, inadequately treated, or has no documentation of having received treatment; mother was treated with erythromycin or other non-penicillin regimen<sup>§</sup>; or mother received treatment <4 weeks before delivery.

**Recommended Evaluation**

CSF analysis for VDRL, cell count, and protein.<sup>‡</sup>

CBC and differential and platelet count.

Long-bone radiographs.

A complete evaluation is not necessary if 10 days of parenteral therapy is administered. However, such evaluations might be useful; a lumbar puncture might document CSF abnormalities that would prompt close follow-up. Other tests (e.g., CBC, platelet count, and bone radiographs) may be performed to further support a diagnosis of congenital syphilis. If a single dose of benzathine penicillin G is used, then the infant must be fully evaluated (i.e., through CSF examination, long-bone radiographs, and CBC with platelets), the full evaluation must be normal, and follow-up must be certain. If any part of the infant's evaluation is abnormal or not performed or if the CSF analysis is rendered uninterpretable because of contamination with blood, then a 10-day course of penicillin is required.

**Recommended Regimens**

Aqueous crystalline penicillin G, 100,000–150,000 units/kg/day, administered as 50,000 units/kg/dose IV every 12 hours during the first 7 days of life and every 8 hours thereafter for a total of 10 days. Alternatively, procaine penicillin G, 50,000 units/kg/dose IM in a single daily dose for 10 days. Alternatively, benzathine penicillin G, 50,000 units/kg/dose IM in a single dose.

Some specialists prefer the 10 days of parenteral therapy if the mother has untreated early syphilis at delivery.

**SCENARIO 3.** Infants who have a normal physical examination and a serum quantitative non-treponemal serologic titer the same or less than four-fold the maternal titer and the mother was treated during pregnancy, treatment was appropriate for the stage of infection, and treatment was administered >4 weeks before delivery; and mother has no evidence of reinfection or relapse.

**Recommended Evaluation**

No evaluation is required.

**Recommended Regimen**

Benzathine penicillin G, 50,000 units/kg/dose IM in a single dose

**SCENARIO 4.** Infants who have a normal physical examination and a serum quantitative non-treponemal serologic titer the same or less than four-fold the maternal titer and the mother's treatment was adequate before pregnancy, and mother's nontreponemal serologic titer remained low and stable before and during pregnancy and at delivery (VDRL <1:2; RPR <1:4).

**Recommended Evaluation**

No evaluation is required.

**Recommended Regimen**

No treatment is required; however, some specialists would treat with benzathine penicillin G 50,000 units/kg as a single IM injection, particularly if follow-up is uncertain.

\*Source: CDC. *Sexually Transmitted Diseases Treatment Guidelines*, 2010

<sup>†</sup>The absence of a four-fold or greater titer for an infant does not exclude congenital syphilis.

<sup>‡</sup>CSF test results obtained during the neonatal period can be difficult to interpret; normal values differ by gestational age and are higher in preterm infants. Values as high as 25 white blood cells (WBCs)/mm<sup>3</sup> and/or protein of 150 mg/dL might occur among normal neonates; some specialists, however, recommend that lower values (i.e., 5 WBCs/mm<sup>3</sup> and protein of 40 mg/dL) be considered the upper limits of normal. Other causes of elevated values should be considered when an infant is being evaluated for CS.

<sup>§</sup>A woman treated with a regimen other than those recommended in these guidelines for treatment should be considered untreated.

<sup>¶</sup>If the infant's nontreponemal test is nonreactive and the likelihood of the infant being infected is low, certain specialists recommend no evaluation but treatment of the infant with a single IM dose of benzathine penicillin G 50,000 units/kg for possible incubating syphilis, after which the infant should receive close serologic follow-up.

<sup>†</sup>Some specialists would not treat the infant but would provide close serologic follow-up in those whose mother's nontreponemal titers decreased four-fold after appropriate therapy for early syphilis or remained stable or low for late syphilis.

Tetracycline and doxycycline are generally contraindicated during pregnancy in that they impair long-bone development and stain decidual teeth in the newborn.<sup>196</sup> Furthermore, tetracycline can cause hepatic toxicity when renal dysfunction is already present. The use of erythromycin instead of BPG is currently not advised due to the increasing reports on macrolide resistance exhibited by *T. pallidum* strains.<sup>190</sup> Concern for use of erythromycin is also associated with the possible erratic transplacental transfer of the drug to the fetus.<sup>197–199</sup> Currently, no data are available to support the use of azithromycin or ceftriaxone to treat CS.

Several hours after treatment with BPG has begun, adult patients might manifest the symptoms of the Jarisch–Herxheimer reaction, which consist of fever, myalgia, headache, hypotension, tachycardia, and transient exacerbation of cutaneous lesions.<sup>186</sup> Such manifestations normally last for 24–36 hours and are currently hypothesized to be caused by the release of proinflammatory components (i.e., lipoproteins, since *T. pallidum* does not synthesize lipopolysaccharide)<sup>200–203</sup> by dying and/or killed treponemes. In pregnant women, the Jarisch–Herxheimer reaction has also been associated<sup>1204</sup> with intrauterine contraction; episodes of tachycardia and deceleration in the fetus heartbeat and overall decrease of fetal movement. Wendel<sup>196</sup> suggested that women diagnosed with syphilis that have already entered their third-trimester pregnancy should undergo sonographic evaluation of the fetus condition and, if hepatomegaly or signs of hydrops are detected, they should be hospitalized for fetal monitoring during the first 24 hours following penicillin administration. If evidence of fetal compromise is detected before penicillin administration, physicians should consider delivering the infant by caesarian section and then treating both mother and newborn separately.<sup>196</sup>

Prolonged treatment of the infant after childbirth could be necessary if treatment of the mother was started within the last 4 weeks of pregnancy. It is possible, in fact, that if penicillin administration is started during the last weeks of pregnancy, the physiological phenomena that accompany pregnancy progression (i.e., increased renal clearance and plasma volume) might alter penicillin pharmacokinetics and result in lower serum and CSF concentration of BPG in both mother and fetus and diminish the effectiveness of the treatment during the final stage of pregnancy.<sup>205</sup>

## TREATMENT OF THE NEWBORN

The diagnosis of CS is complicated by the transplacental transfer of maternal non-treponemal and treponemal antibodies to the fetus. Treatment decisions must be made on the basis of several criteria, which include identification of syphilis in the mother, adequacy of maternal treatment, presence of clinical, laboratory, or radiographic evidence of syphilis in the infant; and comparison of maternal (at delivery) and infant non-treponemal serologic titers.<sup>187</sup> All infants born to mothers who have reactive non-treponemal and treponemal test results should be evaluated with

a quantitative non-treponemal serologic test performed on infant serum because umbilical cord blood can become contaminated with maternal blood and could yield a false-positive result. Conducting a treponemal test on a newborn's serum is not necessary. All infants born to women who have reactive serologic tests for syphilis should be examined thoroughly for evidence of CS.<sup>187</sup> Pathologic examination of the placenta or umbilical cord by using specific fluorescent anti-treponemal antibody staining is suggested. Dark field microscopic examination or DFA staining of suspicious lesions or body fluids (e.g., nasal discharge) also should be performed.<sup>187</sup> Each of the scenarios described in Table 92.7 leads to a recommended evaluation and treatment of the newborn. In limited resource settings, if there is evidence of untreated maternal syphilis, the newborn should be treated.<sup>78</sup>

## FOLLOW-UP MANAGEMENT

Seroreactive infants should receive a non-treponemal test every 2–3 months until the test becomes non-reactive or the titer has decreased four-fold.<sup>187,206,207</sup> If the infant was not infected, and the reactive test result was caused by passive transfer of maternal IgG antibody, non-treponemal antibody titers should decline 3 months after birth and should be non-reactive after 6 months.<sup>187</sup> The same trend should be expected if the infant was infected but adequately treated. The serologic response after therapy might be slower for infants treated after birth. If these titers are stable or increase after age 6–12 months, the child should be evaluated again for syphilis, given a CSF examination, and treated with a 10-day course of parenteral penicillin G.<sup>187</sup> The use of treponemal tests to evaluate treatment response is not recommended, because an infected child can remain positive despite effective therapy in that passively transferred maternal treponemal antibodies can be present in an infant until 15 months of age. A reactive treponemal test after 18 months of age is diagnostic of CS. If the non-treponemal test is non-reactive at this time, no further evaluation or treatment is necessary. If the non-treponemal test is reactive at age 18 months, the infant should undergo reevaluation and treatment for CS.<sup>208</sup> Infants whose initial CSF evaluations are abnormal should undergo a repeat CSF evaluation approximately every 6 months until the results are normal. A reactive CSF VDRL test or abnormal CSF indices that cannot be attributed to other ongoing illness requires retreatment for possible neurosyphilis.<sup>187</sup>

### Summary

Congenital syphilis (CS) is still a public health problem. According to WHO more than two million pregnant women are infected with syphilis and up to 69% of those not treated will result in adverse pregnancy events, and CS. Screening of pregnant women for syphilis and treatment with penicillin is an effective measure to prevent CS. Rapid, on-site diagnosis with rapid syphilis tests is a cost-effective tool for screening.

## Introduction

About 80–90% of fertile couples achieve pregnancy within 1 year and 95% within 2 years of regular, unprotected intercourse. Approximately, one in six couples (15%) face the problem of infertility at sometime in their reproductive lives and seek advice of a gynecologist,<sup>1</sup> attend a family planning or infertility clinic.

Infertility is defined as the inability to conceive in 1 year of regular co-habitation without using any contraceptive. Infertility is primary when the woman has never been pregnant and secondary when the woman fails to conceive following one or more pregnancies or abortion/miscarriage. The problem of infertility involves one or both the partners who need to be investigated simultaneously, counselled, and treated appropriately. This saves time and is cost effective.

Main causes of infertility in women include decreased ovarian reserve, ovulatory disorders, tubal injury (blockage or paratubal adhesions), uterine factors, immunological aberration, or a systemic illness. Important causes of infertility in males include genital injury, infections of semen, testes and accessory glands, genital tract obstructions, varicocele, genital malformations, endocrine and metabolic diseases, drug use and abuse, and psychiatric conditions. Primary infertility mostly can be due to chromosomal abnormality, congenital malformation and or endocrinopathies or can be idiopathic. STI pathogens cause pelvic inflammatory disease (PID) leading to tubal blockage, which is mostly responsible for secondary infertility in female. Tubal factor in infertile women accounts for 30% of the cases. There is a suggestion in the literature that genital tract infection or STI could damage hemato-testicular barrier and elicit formation of antisperm antibodies. Secondary infertility due to STIs is more common and is primarily due to chlamydial or gonococcal causes leading to PID–tubal factors.

Several data-based evidences indicate that sexually transmitted infections reduce fertility both in males and females. STD-related infertility occurs three times more often in Africa than in other parts of the world. STIs affect human fertility primarily through infections of the female upper genital tract and less frequently, through obstructions of vas deferens in the male.

It is important to know that in most of the developing countries normal gynecological check up does not include routine testing for important STIs like *Chlamydia trachomatis* or gonorrhea that are most likely to affect fertility.

Many young people do not seek treatment because of fear of public disclosure, associated shame and guilt and repercussions from angry parents and community elders. Asymptomatic nature of the disease does not allow early detection and treatment of these infections, thus leading to their sequelae like PID and infertility as a result.

## Epidemiology

Though a link between STIs and infertility has been known far more than a century, the high magnitude of STI-related infertility has only been appreciated lately throughout the world. Sub-Saharan Africa has the highest prevalence of STI-related infertility. A study between 1979 and 1984 in 25 countries revealed that as many as 64% infertile couples were afflicted with a STI in Africa and up to 38% in other parts of the world.<sup>1</sup> In USA, over 100,000 women become infertile each year because of PID.<sup>2</sup> The risk factors for acquiring these infections are young age at the commencement of sexual activity, multiple sex partners, non use of barrier contraceptives, and low socio-economic status. Sex workers and those infected with HIV are at the highest risk.<sup>3,4</sup> Sexually transmitted infections may cause infertility by several mechanisms in both males and females, and different organisms influence fertility in different ways. (Table 93.1, 93.2 and 93.3)

**Table 93.1:** Organisms Affecting Fertility

- *Chlamydia trachomatis*
- *N. gonorrhoea*
- *Trichomonas vaginalis*
- Bacterial vaginosis
- HIV infection
- HPV
- HSV
- *M. hominis*, *U. urealyticum*, *M. genitalium*

**Table 93.2:** The Organs Involved and Clinical Features

Men
Primary site: urethra
Secondary site: upper genital tract, testes
Clinical feature: infertility due to blockage of the passage and sperm dysfunction
Females
Primary site: cervix
Secondary site: upper genital tract
Clinical: infertility, ectopic pregnancy, chronic pelvic pain and PID

### Etiological Organisms/Sexually Transmitted Agents that may Cause Infertility

The main sexually transmitted organisms responsible for infertility are *Neisseria gonorrhoeae* and *Chlamydia trachomatis* (CT). Syphilis may cause infertility, but normally this disease is associated with bad obstetric history in the form of late abortions, stillbirth, and neonatal syphilis.

*Trichomonas vaginalis* although is a sexually transmitted pathogen but its impact on fertility is minimal. *Mycoplasma hominis*, *Ureaplasma urealyticum*, aerobes, and anaerobes are present in the genital tract, but are not usually transmitted sexually. They may act as co-factors in those who have acquired a STI and indirectly contribute to infertility by further damaging the structures in the genital tract.<sup>3,4</sup> Less frequently male infertility is due to epididymo-orchitis, mostly caused by *Escherichia coli*. Uropathogenic *E. coli* are more likely than commensal *E. coli*

to be shared with a current heterosexual sex partner. Both sexual behaviors and a bacterial virulence factor can cause the disease.<sup>5,6</sup>

Viruses like HIV, HSV, and HPV though have no direct effect on genital tract, may not cause inflammation but may contribute to infertility by affecting the sperm count and motility and worsening the course of other co-existing STIs.

### Pathogenesis of Infertility

#### IN MALES

Infections of male genito-urinary tract account for about 15% of the case of male infertility.<sup>1</sup> Infections can affect different sites of the male reproductive tract, such as the testis, epididymis and male accessory sex glands. Spermatozoa themselves subsequently can be affected by urogenital infections at different levels of their development, maturation, and transport by several mechanisms, such as sperm nuclear condensation, nuclear fragmentation, decreased sperm motility, and apoptosis.<sup>7</sup>

#### IN FEMALES

Acute cervicitis caused by *N. gonorrhoeae* and/or chlamydia if it causes symptoms is treated promptly. Asymptomatic and chronic cervicitis form a reservoir for bacteria and can impair sperm functions as the sperms move up to the fallopian tubes. Aerobic and anaerobic organisms normally present in the vagina also ascend in a piggy-back fashion with these organisms setting up

**Table 93.3:** Summary of the Possible Associations Between Some Microbiological Agents and Infertility

Microorganism	Female infertility			Male infertility		
	Cervical/vaginal	Uterine	Tubal/pelvic	Testes/epididymis <sup>a</sup>	Prostate/accessory glands	Semen alterations/sperm damage
<i>C. trachomatis</i>	Definite	Definite	Definite and very common	Definite	Doubtful	Possible
<i>N. gonorrhoeae</i>	Definite, but less studied	Definite	Definite	Definite	Probable	Probable
<i>M. hominis</i>	Probable	Possible	Still to be defined	Doubtful	Doubtful	Doubtful
<i>U. urealyticum</i>	Probable	Possible	Still to be defined	Doubtful	Doubtful	Doubtful
<i>M. genitalium</i>	Probable	Possible	Most probable	Doubtful	Doubtful	Attaches to human sperm
Bacteria associated with vaginosis	Possible	Possible	Probable; no associations with specific organisms	Doubtful	Doubtful	Doubtful
<i>T. vaginalis</i>	Possible cofactor	Doubtful	Possible cofactor	Doubtful	Doubtful	Probable under specific conditions
Human papilloma virus	Defined through CIN	Defined through CIN	Improbable	Doubtful	Doubtful	Association needing further investigation
Herpes simplex virus	Doubtful	Doubtful	Association needs further investigations	Doubtful	Doubtful	Probable

Modified from Pellati et al. 2008.<sup>49</sup>

secondary infections in the fallopian tubes. Chlamydial infection is asymptomatic in female in 75% cases, but it causes devastating damage to the fallopian tubes much more than that caused by gonorrhea.

Initially, these bacteria cause endosalpingitis. During the healing process, adhesions form in the lumen. Extensive damage causes fibrosis and peritoneal adhesions leading to tubal blockage or narrowing and stricture formation. All these result in tubal infertility, ectopic pregnancy, and chronic pelvic pain. The external adhesions are seen in the form of fibrous band extending from the right fallopian tube to the undersurface of the liver known as Fitz–Hugh–Curtis syndrome, or perihepatitis.

PID is a clinical syndrome of polymicrobial etiology responsible for tubal damage in 30–40% of infertile women. The rising incidence of PID in recent years strongly correlates with increasing prevalence of STIs and tubal-related infertility.<sup>1</sup> It was observed that 17% women with clinical evidence of PID diagnosed laparoscopically were infertile as compared to none who did not suffer from PID. The proportion of women with infertility was dependent on the number of episodes of PID, its severity and type of organisms involved.<sup>8</sup> In the developed countries, 75% women below 25 years who developed PID were found to have suffered from STIs. The tubal block occurred in 12.8% of patients following one attack of PID, 40% with two attacks and as many as 75% following three or more episodes.<sup>4,8,10</sup> On investigating the association between the lower genital tract infection and infertility, it was observed that most women with tubal infertility did not reveal a history of acute pelvic infection, but sub-clinical PID with mild abdominal pain was observed in 27%.<sup>10,11</sup>

In developing countries, genital tuberculosis in females adds to tubal infertility but this is not supposed to be sexually transmitted.

## N. GONORRHOAE

### In Males

Until recently, *N. gonorrhoeae* was the commonest genital infection. Initially, this infection is limited to the lower genital tract causing urethritis and epididymitis. The diagnosis is easy by studying urethral swab, using Gram-stain, culture, and a NAAT. In a smear, gram-negative intracellular kidney-shaped diplococci are recognized. Prompt treatment cures acute infection. If untreated, the infection spreads to the upper genital tract and causes orchitis and testicular dysfunction. The blocking of the vas leads to oligo- or azoospermia. Unilateral epididymo-orchitis is associated with 23% infertility, whereas bilateral infection causes infertility in 40% cases.<sup>12</sup>

### In Females

In females, *N. gonorrhoeae* was the most common STI accounting for up to 50% tubal infertility in the preantibiotic era. The incidence now has dropped to 10–15%. In UK, its incidence is as low as 10/1000 in women between 15 and 29 years of age.

Recently, penicillinase-producing *N. gonorrhoeae* (PPNG) that causes management problem is becoming more prevalent in south and South-East Asia and Africa. These organisms are transported to other countries through travelers.<sup>9,11</sup> Various studies reveal that 27–39% cases of PID are now caused by chlamydia and 19–26% by *N. gonorrhoeae*.<sup>3,10</sup>

*N. gonorrhoeae* initially causes urethritis, cervicitis and salpingitis. During the healing process, the mucosal adhesions narrow the tubal lumen or cause blockage and peritoneal adhesions. The reduced frequency of coitus due to dyspareunia produced by pelvic inflammatory mass contributes to infertility. Cytokines IL-1a, IL-1b, and TNF- $\alpha$ , produced by tubal epithelial cells after challenge with *N. gonorrhoeae*, may contribute to the genesis of gonococcus-induced infertility.

*N. gonorrhoeae* also helps other organisms present in the vagina to ascend to the fallopian tubes and set up secondary infection. Once this happens, it is difficult to detect and culture *N. gonorrhoeae* from the tubal secretions. Early treatment can prevent tubal damage. In developed countries, PID due to gonococcal infection has declined considerably due to early treatment as well as preventive measures like barrier contraceptives.

## CHLAMYDIA TRACHOMATIS (CT)

*C. trachomatis* is an obligate intracellular bacterium and has a biphasic life cycle characterized by an elementary body (EB) with infective capacity and reticular body (RB) that replicates in eukaryotic cells. *C. trachomatis* has a worldwide distribution, affecting both sexes but has a much greater impact on females than on males. Chlamydial infections may, in many cases, remain silent. This pathogen particularly affects young women and sexually active adolescents. Serovars A, B, Ba, and C are associated with endemic trachoma, while serovars L1, L2, and L3 are associated with lymphogranuloma venereum (LGV). Serovars D through K are the major causes of non-gonococcal urethritis and epididymitis in men and may induce Reiter syndrome, proctitis, and conjunctivitis in both men and women, and cervicitis, urethritis, endometritis, salpingitis, and perihepatitis in women.

### In Females

*C. trachomatis* is believed to be one of the major causes of cervical factor infertility, as a result of the alterations of the epithelium and mucus composition, and by the presence of inflammatory cells; although, the overall impact of cervical disorders on fertility still needs to be assessed. Keltz et al.<sup>11</sup> reported chlamydia to be the most common cause of tubal infertility with 296.5 cases per 10,000 population in United States. Amongst PID cases, 30% of the hospitalized cases and 50% of OPD cases had chlamydial etiology.<sup>14</sup> Another study observed this organism in 53% of women with PID.<sup>15</sup> Most women with chlamydial infection are young and sexually active. Up to 70–75% of them are asymptomatic.<sup>16</sup>

Acute cervicitis is frequently a self-limiting condition, remains asymptomatic, unnoticed and therefore untreated.<sup>17,18</sup> In 20%, the

infection ascends to the upper genital tract and sets up chronic PID. It then causes more extensive damage to the fallopian tubes as compared to that caused by gonorrhea.<sup>8</sup>

Chlamydiosis is a major cause of tubal obstruction and ectopic pregnancy, and can result in PID, adnexitis, local or diffuse peritonitis, and formation of adhesions which may disrupt the passing of oocytes through the tubes; so this infection in women interferes seriously with human reproduction. The fact that such conditions often occur in adolescents and may preclude them from having a reproductive future, has put this infection under the spotlight.<sup>19</sup> The chlamydial 10 and 57 kDa HSP (cHSP10 and cHSP57/60, respectively) show remarkable homology to human proteins. Thus, this expected cross-reactivity between the human HSP60 and the bacterial cHSP60 leads to the formation of antibodies against the HSP60 in the serum and follicular fluid of women exposed to *C. trachomatis*. High homology to a human protein may cause autoimmune infertility that can make even IVF ineffective.

These antibodies also have a negative impact on embryonal growth, and increase the probability of adverse pregnancy outcomes. HSP57/60 also has been found to induce trophoblast apoptosis by stimulating the toll-like receptor 4 (TLR4), which naturally mediates immune responses in placenta.<sup>18</sup> Women with serum antibodies against HSP60 and positive for *C. trachomatis* seem to have a greater probability of tubal scarring and ectopic pregnancy, compared to women who are only seropositive for anti-chlamydial antibodies. There also seems to be a cross-reactivity between HSP10 and an embryonic protein, the early pregnancy factor (EPF), and this may cause abortions. cHSP10 too, probably correlates with the severity of the disease in women and so with the presence of tubal factor infertility.<sup>20</sup> HSP60 has consequently been proposed as a prognostic criterion for the assessment of chlamydial infections in women and, together with other humoral parameters, as a means for a prior diagnosis of tubal factor infertility.<sup>21</sup> Genetic conditions involving immune regulation pathways may have an important role in the whole process of *C. trachomatis*-induced damage. Some variants of the gene that controls IL-10 production may be involved in the impairment of the immune response against the bacterium.<sup>22</sup> Finally, a strong antibody response against *C. trachomatis*, but no sign of current or chronic infection was found in women with tubal factor infertility (TFI), indicating that previous infections may have resulted in permanent damage and occlusion of the fallopian tubes. Antibodies to *C. trachomatis* were present in 23% of women with tubal factor infertility as compared to the figure of 15% in women with normal tubes. None of the infertile women had evidence of infection in the past.<sup>16</sup> While these small studies fairly suggest an association, there have not been the detailed longitudinal studies that would allow accurate estimates of the actual risk of infertility after *C. trachomatis* infection.

Given the potential for morbidity from ectopic pregnancy and tubal infertility the case for screening for chlamydia among those most at risk is strong.<sup>23</sup> Enzyme immunoassays for detecting chlamydial antigen and direct nucleic acid probe assays are the most

widely used and can evaluate large number of samples. Nucleic acid amplification tests for chlamydia, including polymerase chain reaction and transcription-mediated amplification assays, are more sensitive and highly specific. Although there is no absolute “gold standard” for chlamydia tests, amplification assays have a sensitivity of at least 90% compared with 60–70% for culture and 60% for antigen assays.<sup>23</sup>

Treatment with a single oral dose of azithromycin 1g or doxycycline 100 mg twice daily for 7 days eradicates acute infection. However, recurrences do occur. Therefore, vaccine against this infection is suggested as the only option. More research and development of vaccine may be the answer if tubal infertility due to *C. trachomatis* is to be prevented before infection is acquired.<sup>17</sup>

## In Males

In males, with decreased prevalence of gonococcal infections, *C. trachomatis* is now the commonest bacterial infection causing infertility. Epidemiology of CT infection in a male is difficult to evaluate because 50% men remain asymptomatic and organisms grow only in tissue culture.<sup>24</sup> With the availability of sensitive NAATs and serum and semen antibody estimation, the importance of this organism is being increasingly recognized.

*C. trachomatis* can be detected in the urethral swab and urine, when urethritis occurs. It is however difficult to detect chlamydial DNA in the secretions of the male accessory glands. IgG and IgA antibodies in the serum and semen are then the only evidence of infection in the upper genital tract.<sup>25,26</sup> By routine testing for chlamydia in infertile couples, Bennett et al.<sup>27</sup> revealed evidence of infection in 39% males. A study of 40,094 men from a STD clinic revealed prevalence of CT in 10.3% men below 29 years of age.<sup>27</sup> In another study, CT infection was seen in as much as 8.3% of male partners of infected couples as compared to only 2.5% in the control group.<sup>28</sup> More than 101 million new cases of chlamydia occur each year world wide (WHO 2005), but as mentioned earlier, 75% infected women and 50–70% men remain symptom less and are not recognized. In one study, infection accounted for 15% cases of male infertility.<sup>7</sup>

Acute infection causes urethritis, but this does not interfere with fertility of those fully treated. Chronic infection can cause damage at various sites in the genital tract and by different mechanisms. The evidences suggest that in the humans *C. trachomatis*, causes infertility by a route independent of structural damage to the genital tract. This is shown by *in vitro* studies.<sup>29</sup> The primary site of infection is the urethra, causing urethritis in 30–40% in men. The urethral swab and urine culture can detect its presence. Epididymitis follows in 40–50%, but uncontaminated specimen is difficult to obtain for its detection.<sup>25</sup> A causative link between chlamydia and epididymo-orchitis has been reported in 11–35% of men. The presence of antibodies in the semen and serum indicate past infection. The chlamydia attaches to the leukocytes and sperms as shown by electron microscopy and this is responsible for transmission of infection to the female partner.

Evidences based till date have shown that chlamydia causes increased semen volume and pus cells thereby indicating

inflammation and release of cytokines. It decreases the sperm motility and causes apoptosis (death) by its lipopolysaccharide component which has spermicidal effect. The measurable intracellular changes in the tyrosine phosphorylation of sperm protein in response to the bacteria are also detrimental to the sperm functions.<sup>30,31</sup> Fragmentation and sperm nuclear condensation interfere with fertilization process. Dimitrova et al.<sup>26</sup> proved that CT can provoke formation of anti-sperm antibodies that impair fertility. A few studies<sup>7,29</sup> however have denied any detrimental influence of chlamydial infection on fertility, but this can be explained on account of different methods used to obtain specimens and tissues for its detection. Most studies conclude chlamydial infection as one of the important additional causes of infertility both in men and women.

### TRICHOMONAS VAGINALIS

*T. vaginalis* has a worldwide distribution and is a common infection of the male genital tract. It can rarely cause urethritis and perhaps prostatitis and other genital tract disorders. Evidence suggests that men with trichomoniasis have decreased sperm motility, more abnormal sperms, higher semen viscosity and particulate debris, and diminished integrity of the spermatozoan membrane.<sup>32</sup> However, long-term consequences of trichomoniasis are unknown, and overall evidence suggests that its impact on male fertility may be minimal.<sup>33</sup> The clear association between the presence of *T. vaginalis* and leukorrhea, and the significant association with bacterial vaginosis, have suggested that the presence of trichomonads might have a favorable effect on bacterial growth. Trichomoniasis is associated with mild vaginal and cervical damage, and does not seem capable of producing cervical factor infertility. It has also been associated with adverse pregnancy outcomes.<sup>34</sup> Other than bacterial vaginosis, *T. vaginalis* promotes the action of *M. hominis* by transporting the bacterium inside the protozoa cell and by permitting its active replication. This offers protection to the bacterium from the action of the immune system and the effects of therapies, and favors its spread by transporting it through the genital tract, as a clear and important example of a symbiotic relationship between human pathogens.<sup>35,36</sup>

### MYCOPLASMAS

The role of *M. hominis* and *U. urealyticum* is less clear. These are residents of the lower genital tract in 50% of sexually active females. However, only 7% are involved in PID. They may act as co-factors associated with other infections.<sup>10,16</sup>

*Mycoplasma genitalium* is another organism that has recently been found to be sexually transmitted and is harmful to both the sexes. It is isolated from urine in the male and is known to cause non-gonococcal urethritis. It is present in 56% of male partners with infected women and 32% among female partners of infected males. In a study from Denmark, antibodies to *M. genitalium* were present in 17% of the women with tubal factors infertility as compared

to the figure of 4% for women with normal tubes.<sup>16</sup> The difficulty in detecting its presence lies in the limitations of cultivating the organism and non-availability of commercial serological kits. The slow growing nature of *M. genitalium* allows overgrowth of other organisms. PCR is now employed to detect this mycoplasma. A British study showed 13% women with PID were PCR positive for this organism, compared to the control group.<sup>37</sup> In Kenya, 7% with laparoscopically proved PID were PCR positive. *M. genitalium* can grow independent of *N. gonorrhoeae* and chlamydia. *M. genitalium* is strongly associated with cervicitis, endometritis, and serologically with salpingitis-pelvic inflammatory disease (PID), and may account for a number of cases of infertility.<sup>16,37</sup>

*U. urealyticum* is associated with the production of reactive oxygen species, even in absence of leukocytospermia, and *M. genitalium* can attach to human spermatozoa and thus could be carried out by motile sperm. This ability may be important in the process of causing female genital diseases and infertility.<sup>38</sup>

### GARDNERELLA VAGINALIS

*G. vaginalis* seems to be very common in the genital tract of men with suspected infertility, and is also frequent among infertile men and even more among their wives; the significance of this data, however, remains unclear since the bacterium is also common amongst normofertile individuals.

Bacterial vaginosis (BV) in a woman is not uncommon, but the role of the organisms responsible for BV in infertility is not clear. Microorganisms associated with bacterial vaginosis, apart from *M. hominis* and *U. urealyticum*, include *G. vaginalis*, *Mobiluncus* spp., *Bacteroides* spp. (excluding *Bacteroides fragilis*), *A. vaginae*, and *Peptostreptococcus* spp. and may reach the genital tract in several manners. There is the speculation that these organisms adversely affect the quality of sperms deposited in the vagina and their fertility potential.<sup>39</sup> Wiesenfel et al.<sup>10</sup> reported that 15% women with BV developed endometritis and PID. These organisms not only cause tubal damage, but also interfere with implantation of the fertilized egg.

### VIRUSES

#### Human Immunodeficiency Virus

HIV may impair semen parameters by itself and certainly deteriorates the outcome of concomitant genital infections; in addition, the specific anti-HIV therapies can damage the male reproductive system. In a study of 24 HIV-positive and 60 HIV-negative men, HIV-infected men had substantially reduced sperm counts and increased number of abnormal sperms.<sup>40</sup> Furthermore, semen parameters of HIV-infected men are inversely correlated with the extent of disease progression.<sup>41,42</sup>

HIV has a negative impact also on female fertility, but it is not clear to what extent this is due to the activity of the virus itself, or to other genital infections, whose course is adversely affected in the presence of HIV infection, or even to the side effects of therapies. In endemic regions of Africa, HIV infection appears to reduce

female fertility by 16–26%, producing higher rates of involuntary childlessness and longer intervals between births.<sup>43</sup> Tubal disease among HIV-infected women appears to be secondary to infection with other STIs, such as chlamydial infection or gonorrhea. HIV infection may affect the hypothalamic-pituitary-ovarian axis, causing sub-fertility secondary to hormonal dysfunction. However, these changes have not been observed consistently.<sup>44</sup> If HIV infection produces hormonal dysfunction, it may occur only as the disease progresses to more advanced stages. Recent progress on antiretroviral therapies and on assisted reproduction techniques has made the birth of healthy children from seropositive parents possible.<sup>45</sup>

## Herpes Simplex Virus

The presence of HSV DNA in human spermatozoa, even if in low percentage, was significantly related to poor sperm count and reduced motility.<sup>46</sup> Antiviral treatment of male infertility patients positive for HSV in semen resulted in successful pregnancies. Thus, HSV infection of the male genital tract could explain some cases of male infertility, as a consequence of its association with decreased semen quality.<sup>47</sup>

A significant association seems to exist between serum IgM antibodies against HSV, and the presence of leukocytospermia, although the clinical significance of the later condition still remains unclear. HSV infections, on the other hand, seem to have no significant association with cervical factor infertility.<sup>47</sup> Cherpès et al. indicate a possible association with PID, without specifying the way in which the virus may be involved in the pathogenesis of the disease.<sup>48</sup>

## Human Papilloma Viruses (HPV)

HPVs were found in testicular biopsies of azoospermic men and when present inside sperm cells, they may be related to impaired sperm motility and asthenozoospermia.<sup>49</sup> Alvarez Fernandez et al. found, in 1998, an association between HPV and infertility, particularly between the presence of these agents and tubal factor infertility, and such association, according to the researchers, necessitates further investigations.<sup>50</sup> Obviously these viruses are much more harmful in the cervical region. Surgical procedures for cervical intraepithelial neoplasia (CIN), though less invasive nowadays, still cause cervical mutilations that compromise fertility.

## Prevention

With the above observations, it is clear that most sexually transmitted infections do contribute to infertility to a variable extent by several mechanisms both in the male and female. In New Zealand, the screening program for chlamydia has reduced the incidence of infection by 50%.<sup>27</sup> Therefore some have suggested screening should also be extended to infertile couples.

Early detection and treatment of asymptomatic cases will prevent ascending infection which really impairs fertility. Sex education to young couples and adolescents indulging in sexual activity and motivating them to use barrier contraceptives will

be a step forward in reducing sexually transmitted infections.<sup>51</sup> In IVF program checking for chlamydia would improve the success rate.

## Conclusion

Infections can damage reproduction in diverse ways. The complexity of these mechanisms can create confusion for epidemiologists interested in the causation of reproductive impairments. For example, chlamydial infection causes infertility through tubal scarring. By the time the infertility is manifest (often years later), the infection has usually been cleared. Meanwhile, other factors associated with chlamydial infection, such as other STIs, social habits of affected women, or environmental conditions, may mistakenly be blamed for the women's decreased fertility.

These complexities raise interesting questions for epidemiologists who study reproduction. For a given infectious agent and outcome: is it prior infection, latent infection, or active infection that is most important? Is it the severity of the infection or the strength of the immune response that damages reproduction? Might non-infectious factors of interest increase the risk of reactivation of a latent infection, or increase the risk of a new infection? Are there risk factors that confound the relation of an infection with the outcome? Are there infections that confound the study of non-infectious exposures and their relationship to fertility or pregnancy?

Although both men and women risk serious consequences, the female reproductive potential seems to be much more at stake. Tubal-pelvic factor infertility has rightfully gained attention as the greatest hazard deriving from infectious diseases.

*N. gonorrhoeae* and chlamydia are mostly responsible for genital tract infections and STI-related infertility. With the incidence of gonorrhoea declining, *C. trachomatis* is the pathogen that has been most intensely related to these particular fertility disorders, and is still considered to be a major social hazard. Acute infections usually do not impair fertility, but a chronic infection, by virtue of damage to the genital tract and impairing sperm morphology and functions can lead to infertility. Unfortunately, 50–75% of infected cases are asymptomatic and are left untreated. *M. genitalium* has lately been discovered to impair fertility, but the role of other mycoplasmas and viruses is less well-known.

It is possible to reduce the infertility rate due to sexually transmitted infections by routine screening of high-risk populations, treating the asymptomatic cases and imparting sex education. The development of a vaccine may be considered as the best option to prevent chlamydial infection-related infertility, but still needs a lot of research.

## Aging, Sexual Behavior, and HIV/STI Risk

Massimo Giuliani

*The worst thing about aging is that you stay young.*  
— J Cocteau, 1958

### Introduction

Aging is generally associated with a decrease in sexual arousal and activity, and studies have shown that the frequency of sexual intercourse decreases with age in both the genders, particularly as a result of physiological changes, as opposed to changes in satisfaction or desire.<sup>1</sup> Indeed, sexual desire continues well into later life for both men and women but can be limited by aging in various ways.

In general, the effect of aging on sexual performance depends upon the physical and mental health of the individual.<sup>2</sup> Nevertheless, many authors agree that the physical changes that occur in older age can modify sexual experiences but do not completely extinguish them.<sup>3,4</sup> The main factors that contribute to a decrease in sexual activity among older individuals are: medication, disease states, physical barriers, negative perception of body image, mental disorders,<sup>5</sup> and some important physiological changes. The main described physiological changes which reduce the sexual performance of the older persons include: the alteration in the vaginal secretions and flattening of the vaginal epithelium in women and erectile dysfunctions in men, whereas other factors do not seem to greatly limit sexual intercourse (Table 94.1).<sup>6,7</sup>

In recent years, sexuality in older groups has solicited the interest of public-health authorities in industrialized countries because of a sudden increase in the incidence of sexually transmitted infections (STI) among persons over 50 and 60 years of age. Despite the fact that aging is usually associated with a decrease in sexual arousal and activity, in recent decades some factors have enhanced the sexual life of individuals in their sixties, seventies, and even eighties. This may have increased the proportion of individuals in mid-life and late adulthood who engage in sexual behavior at-risk for HIV infection and other STIs.

Within the proactive factors currently associated with an extension of sexual activities into late ages (Table 94.2), nowadays, the greatest role seems to be played by the availability of drugs to

enhance sexual performance and the increased social acceptability of sexually active elderly persons.

An extensive survey conducted in Sweden over the past 30 years has shown that the self-reported quantity and quality of sexual experiences among 70-year-olds have improved in recent decades. Men and women from later birth cohorts reported higher satisfaction with sexuality, fewer sexual dysfunctions, and more positive sexual attitudes and practices in later life than those from earlier birth cohorts.<sup>8</sup>

**Table 94.1:** Biological and Physiological Changes Associated with Modifications of Sexual Performance among Older Individuals

	Male	Female
Testosterone level decrease	Yes	Yes
Estrogens level decrease	–	Yes
Desire decrease	Yes	Yes
Penile sensitivity decrease	Yes	–
Penile rigidity decrease	Yes	–
Reduction of vaginal secretions	–	Yes
Reduction of the period of inevitability before ejaculation	Yes	–
Reduction of semen volume per ejaculation	Yes	–
Refractory period extension	Yes	No
Reduction of pre-ejaculatory liquid	Yes	–
Reduction of nocturnal spontaneous erection	Yes	–

**Table 94.2:** Selected Proactive Factors Associated with Sexual Activity in Late Ages

- Extension of life expectancy
- Increased healthy survival
- Improved quality of life and physical and psychological well-being
- Lower impact of drugs for unrelated disorders on sexual performance
- Availability of drugs against sexual dysfunctions
- Improved social acceptability of sexuality in later-life

## Prevalence of Sexual Activity in Older People

Whereas there is extensive literature on the sexuality of adults and young persons, studies on the characteristics and nature of sexuality in older age groups are lacking. Nevertheless, the importance of better understanding the complexity and determinants of the human behaviors associated with the diseases with major impact on the western health systems, stresses the need for extensive investigations to identify the characteristics of sexual behavior along all ages.

Several studies seem to confirm that a high proportion of men and women remain sexually active well into later life. In particular, behavioral studies on sexuality among older adults in Western countries have shown that, although many elderly persons are sexually active over 60 and 70 years of age, in general, older women are less likely to have an intimate relationship and engage in sexual activities than men. Pfeiffer et al. reported that 95% of men aged 46–50 and 28% of men aged 66–71 have sexual intercourse on a weekly basis.<sup>9</sup> Diokno et al. reported that nearly 74% of married men older than 60 remain sexually active.<sup>10</sup> A 1988 study about sexual interest and behavior showed that 62% of men and 30% of women aged 80–102 were still having sex.<sup>11</sup> Recently, Smith et al. reported that, among a small sample of individuals over 70 years of age residing in New York, 18% of women and 41% of men were sexually active.<sup>12</sup>

An additional recent study conducted on a large sample ( $n = 3005$ ) of community-dwelling persons from 57 to 85 years of age, interviewed during the second semester of 2005 and the first quarter of 2006, showed a steady decrease in the prevalence of sexual activity with age and a positive association with self-reported health. However, among the sexually active responders, 67% of those aged 65 to 74 years and the 38.5% of those over 74 years, reported having had sex in the previous year.<sup>13</sup>

Johnson et al. reported that the frequency of sexual intercourses is strongly associated with *having a partner* and is highest among married or cohabiting people. Moreover, 54% of the sexually active men aged 75–85 years reported the use of medication to improve sexual performance.<sup>14</sup>

Some studies have shown that an adult's sexual expression is not age dependent<sup>15</sup> but older individuals are commonly more reluctant than younger ones to talk about sexuality. Moreover, some individuals might be influenced by the cultural context and social acceptability in the community where their sexuality was developed and sexual activity started. By way of example, many older homosexual men have started to engage in sex when having sex with men was socially unacceptable and in some countries also illegal, so that they have learnt to mask their sexual habits.

## Aging, Gender, and Risk of STIs

In general, data from observational studies seem to confirm that among the elderly important differences in sexual risk behavior exist between men and women.<sup>16</sup> Older men have been found to be at greater risk for STIs than older women because of: (i) a

larger number of recent sexual partners; (ii) a disproportionately greater access to sex for money; (iii) sex with a same-sex partner; (iv) greater frequency of sex overseas or with a non-national partner; and (v) the existence of drugs for counteracting the physiological changes associated with a reduction in sexual activity.<sup>17</sup> Moreover, among older men who have sex with men, although the frequency of sex decreases with age, some studies have reported a progressive increase in the frequency of at-risk practices, such as unprotected receptive anal and oral intercourse due to impairment associated with physical and physiological changes (e.g., loss of bodily strength, erectile dysfunction, genital sensitivity decrease). Focus groups conducted with over forty Canadian gays and bisexual men, showed that some age-related issues have an impact on safer sex decision-making even before the age of 50 years. If the decreased attractiveness, widowerhood, the loss of support network from AIDS seem to protect from the risky sex, contrarily, condom fatigue, treatment optimism, inserter invulnerability, depression, and the negative effects of condom-use in keeping erections seem to support the engagement in risky situations.<sup>18,19</sup>

Older women tend to be at risk for STIs because they are less likely to engage in protected sexual intercourse, with respect to same-age men. In Australia, among 1976 men and 462 women over 50 years of age, the proportion of sexually active persons who had used condoms in the preceding 3 months was 54% among men and 19% among women ( $\chi^2 = 63.3$ ,  $p < 0.05$ ).<sup>17</sup>

Some authors have reported that older women are increasingly at risk of STIs during the peri- and postmenopausal period. In this period, STI-related genital symptoms are often nonspecific or absent or may be misclassified as being due to the specific hormonal state. Furthermore, women in this period may not be aware of the risk of infection, with consequent delayed or missed STI diagnosis.<sup>20</sup>

In the United States, among the more than 3200 adults over 50 years of age interviewed in the National AIDS Behavioural Study (NABS) from 1993 to 1994, 7.0% had taken a risk for HIV/STI during the previous year, 83.0% had not used a condom during sex, and 80.0% were not tested for HIV.<sup>21</sup> Moreover, of the 2058 individuals who reported more than two sexual partners in the preceding 5 years, 10.0% were 50–59 years old, 9.0% were 60–69 years old, and 8.0% were over 70 years.<sup>22</sup>

## STIs among Elderly

Since the year 2000, in the industrialized countries sexual behavior has again started to represent an important determinant of morbidity and use of healthcare services in all age groups. A dramatic increase in the incidence of unplanned pregnancies and abortions among adolescents and young adults and a dramatic re-emergence of STIs both in the general population and vulnerable groups, such as MSM and migrants, have been observed.<sup>23–25</sup> Moreover, in Western countries some behavioral studies have shown that millions of men and women over 50 and 60 years engage in sexual behavior at-risk for HIV and other STIs. However, recent data on STIs among older persons are poorly available, and comparable studies and information

on the circulation of STIs within this population group are yet scarce. Nevertheless, data provided by surveillance systems and local surveys conducted in several developed countries since 2000 seem to suggest a progressive increase in the number of older individuals with a new episode of STI among attendees of clinical centers. Generally, in the field of STIs, the term “older patient” refers to persons 50 years of age or older, though in some studies it refers to lower ages.

Some accurate information on STIs among older individuals has been provided by ongoing National STI Surveillance Systems in several developed countries. For example, in the United Kingdom, from 1996 to 2003, the proportion of STIs other than HIV infection among the total reported cases in individuals over 45 years of age increased from 3.7% to 4.3% and the incidence rate of STIs in this age group more than doubled in 2003 compared to 1996. Moreover, for the major STIs this increase has been observed in all age groups over 45 and particularly in individuals aged 55–59 years (Fig. 94.1).<sup>26</sup> A previous study from the United Kingdom had shown that around 8.0% of the new or rebooked patients in a genitourinary medicine clinic in Portsmouth were aged 50 years or older (median 57 years).<sup>27</sup> In the United States, data from Washington State’s STI Surveillance showed that between 1992 and 1998, 1.3% of the cases had been diagnosed among individuals 50–80 years old and that the most common STIs were nongonococcal urethritis in men and genital herpes in women. In this study, older patients were more likely than younger persons to be white, to seek care at private facilities, and to be symptomatic at the clinical consultation.<sup>28</sup>

Among the attendees at a sexual health clinic in Sydney from 1993 to 2003, 40.0% showed genital symptoms, 23.0% and 13.0% requested STI testing and HIV-1 testing/care, respectively. The most common STIs were genital herpes (10.0% women, 6.0% men) and nongonococcal infections (9.0% in both genders).<sup>17</sup>

In Italy, according to data from the STI National Sentinel Surveillance System, around 10.0% of all reported cases have

**Fig. 94.1:** Rates (95% CI) of selected sexually transmitted infections in people aged >44 years in the West Midlands, UK, by year of diagnosis and age group: 1996–2003 (Modified from Bodley-Tickell AT, et al. 2008).

**Fig. 94.2:** Trend of prevalence of HIV-1 infection among 5256 Italian STI patients over 50 years of age, by year; Italy, STI Surveillance System, 1990–2005.

**Table 94.3:** Factors Associated with the Increased Risk of STIs among the Older Individuals

- Lack of information and attitudes about STI prevention
- Changes in social patterns and relationships (single, divorced, separated, or widowed)
- Availability of effective medication against erectile dysfunction
- Improved accessibility to sex for money

been diagnosed in individuals over 50 years of age. From 1991 to 2006, 9845 new cases of STIs were reported in this age group. The median age was 56.7 years (IQR= 53–64 yrs) and the male-to-female ratio was 2:1, higher than that observed in other younger age groups. The most common STIs reported in persons over 50 years were genital herpes and genital warts among men, and unspecified vaginal infections and latent syphilis among women.<sup>29</sup> Moreover, in this population the cumulative prevalence of HIV-1 infection was 5.0% and the trend has shown a progressive increase, particularly after 1995 (Fig. 94.2).

In developed countries, the observed increase in STI incidence among the elderly seems to be associated with specific social and behavioral factors. Data from a behavioral study have shown that these factors range from lack of information and skills to changes in the individual and the social status (Table 94.3).<sup>30</sup>

### Preventative Attitudes among Elderly

The elderly, compared to younger individuals, seem to be less likely to use condoms during sex or to have been tested for HIV. Moreover, in developed countries, older adults generally know less about HIV infection and AIDS than younger people, including how the disease is transmitted.

Older people have been neglected by health educators, overlooked by health workers, and might be excluded from HIV facilities and prevention programs.

Several factors seem to affect the communication between elderly persons and health specialists about sex education and information. Moreover, it is not easy for general practitioners

**Table 94.4:** Reasons Associated with the Lack of Investigation of Sexual Behavior in the Older Individuals

- Sexual history is not included in current anamnesis taken in older patients
- Elderly are not perceived by the physician to be a sexual risk taker
- Reluctance in elderly to disclose sexual health concerns
- Fear and embarrassment
- Lower accessibility to clinical centers

to talk about sex with their patients, often because of a lack of communication skills, which also limits the evaluation of symptoms associated with STIs (Table 94.4).

Moreover, older persons seem to be excluded from the target populations identified for prevention campaigns. Some authors recommended that older people should be encouraged to attend STI facilities by improving accessibility and welcoming them.<sup>31</sup> This is an important public-health goal, particularly today, when sexual activity after the reproductive years is made easier by hormone replacement therapy for women and erectile dysfunction treatment for men.

## Elderly and HIV Infection

Until a few years ago, it was uncommon to read about a case of a new HIV infection in an elderly man, and the cases that did exist were described as anecdotal case reports.<sup>32</sup> However, in the past decade the size of the aged population living with HIV/AIDS has progressively increased worldwide, and the World Health Organization estimates that there are approximately 3 million individuals over 50 years of age living with HIV/AIDS.<sup>33</sup> By 2015, it is expected that around 50% of HIV-infected persons will be older than 50 years.

In Western countries, this progressive aging of the AIDS epidemic has been observed since 2000, also because of some important clinical and epidemiologic changes. The main factors are:

- (a) the introduction of highly activity antiretroviral therapy (HAART) in the mid-1990s and the consequent increase in the survival of persons with HIV infection;
- (b) the tendency of older HIV-infected individuals to transmit the infection mainly to age-peer sexual partners;
- (c) the tendency of HIV-infected individuals who minimize their own sexual risk to be diagnosed late, at an older age; and
- (d) an increase in the number of persons, particularly men, who acquired HIV infection in older age during a prolonged drug-supported sexual activity.

Early in the AIDS epidemic, older persons represented a large proportion of the persons infected through blood products or transfusions, yet this proportion has greatly decreased since the introduction of policies for reducing the risks related to transfusions, especially in Western countries.

In a seroprevalence study conducted in the pre-HAART era among hospital patients over 60 years of age and dead for causes

not related to HIV/AIDS, 6.2% of men and 8.9% of women were HIV-infected, and over 60.0% of these individuals had no identifiable risk factors for HIV infection.<sup>34</sup> Also today, HIV infection in the elderly may remain misclassified until a late diagnosis or unrecognized until the death from other co-causes. In all countries it is very common for healthcare workers to neglect to screen older individuals for HIV. The difficulties in talking about sexuality or occasional sex by the physician with the elderly may lead to false assumptions about risk behavior and to also limit HIV screening. Today, in the United States, according to the recently revised guidelines for routine HIV testing, all adults over 50 years old must be subjected to HIV testing, regardless of risk,<sup>35</sup> and some authors have also recently determined that one time HIV testing is cost-effective in sexually active people over the age of 65 years.<sup>36</sup>

In the United States, AIDS patients older than 50 years represented more than 12.0% of the total reported diagnoses from 1982 to 2007. In 2007 this proportion increased to 17.0% (13% represented by 50 to 59-year-olds and 4.0% by persons over 60 years), and is expected to continue to increase over the next decade.<sup>37</sup>

In Canada, as of December 2006, 8.0% of the new HIV cases and 12.0% of AIDS patients were 50 years of age or older.<sup>38</sup> In Australia, 14.0% of AIDS cases and 17.0% of deaths due to AIDS notified until December 2007 were observed in people over the age of 50 years.<sup>39</sup>

A similar trend has been observed in Europe, where nearly 17% of the persons with AIDS diagnosed between 2001 and 2005 were older than 50 years. The proportion of new HIV diagnoses in this age group has greatly increased, reaching 15.6% in 2006.<sup>40</sup>

In the United Kingdom, in 2007, 8.5% of new HIV infections were diagnosed in men over 50 and nearly 4% in women in the same age group.<sup>41</sup>

In Italy, according to data from AIDS surveillance system, from 1982 to 2005, 8.8% of the notified cases were observed among persons over 50 years of age, and this proportion has increased over time, from 4.9% in 1982–1990 to 15.9% in 2000–2005. Among older Italian AIDS patients there is a higher proportion of cases due to sexual transmission, than among younger patients.<sup>42</sup> In a study from Italy between January 2004 and March 2007 among individuals over 50 years of age with a new HIV diagnosis, higher proportion of them were in a more advanced stage of HIV infection. Majority of them reported heterosexual exposure and were never tested for HIV before.<sup>43</sup>

Since the beginning of the AIDS epidemic, older persons with HIV have had a higher morbidity, higher fatality rates, and a shorter AIDS-free survival than adults and young persons. Before the introduction of HAART, large multicenter studies showed that from 13.0% to 14.0% of HIV-infected individuals over 50 years of age died within 1 month of the AIDS diagnosis, twice the proportion observed in persons aged 13–49 years (6.0%).<sup>44,45</sup> This difference was largely explained by late diagnosis and comorbidity, though a weaker immunological response in terms of CD4+ cell reconstitution also seems to have played a

**Table 94.5:** Major Clinical Characteristics of Older (Age >50 years) Versus Younger HIV-infected Individuals

- Decreased interval between HIV and AIDS diagnoses
- Higher rates of concurrent illness (comorbidity)
- Increased mortality rates
- Faster viral suppression during HAART
- Higher rates of adherence to HAART
- Slower CD4+ cell count positive slope during HAART
- Increased risk of severe adverse events associated with HAART
- Increased risk of CNS HIV-associated illness (Encephalopathy, ADC, cognitive impairment)

CNS, central nervous system; HAART: highly active antiretroviral therapy; ADC: AIDS dementia complex.

role. The main differences between older and younger persons with HIV, in terms of HIV disease presentation and course, are listed in Table 94.5.

## Aging and HIV Disease

Many years ago, Italian researchers established in a longitudinal study that the natural course of HIV disease is modified by the increasing age at the diagnosis (Fig. 94.3), also as a result of basically immunological changes that are naturally associated with aging.<sup>46</sup>

In healthy older persons, a natural involution of the thymus occurs and the thymic volume is significantly lower in persons 50 years of age and older than younger individuals.<sup>47</sup> The production of naïve T cells also tends to decline with age; thymic output is minimal after the age of 55 years,<sup>48</sup> and the populations of memory T cell and functioning CD8+ cytotoxic cells are significantly reduced.<sup>49</sup> Thymic function and production of naïve T cells may be altered and inhibited during HIV disease.<sup>50</sup> For these biological and immunological differences, the progression of HIV infection in the elderly may be faster than among younger persons.

Many studies have suggested that older patients may not respond as well to HAART as younger patients; particularly, the risk of clinical progression to AIDS has been reported to be 1.5 times higher and the immune restoration in terms of positive recovery of CD4+ cells may be lower despite a faster virological

success.<sup>51</sup> That older patients are more likely than younger patients to achieve HIV-1 RNA levels lower than 500 copies/mL was confirmed in a large cohort study that compared immunological and virological responses to, and tolerability for HAART in 997 patients, 50 years of age or older and 4093 younger patients. The study showed that the virological success in the older patients was sustained by a better adherence to HAART, despite a higher risk of adverse events, such as metabolic, hematologic, and renal abnormalities.<sup>52</sup>

Older patients may be more likely than younger patients to develop significant toxicities, including dyslipidemia, impaired glucose metabolism, pancreatitis, neuropathy, hepatotoxicity, and lactic acidosis because older people are more likely to have comorbidities, including cardiovascular disease, renal disease, diabetes, bone loss, and obesity, which complicate the use of antiretroviral therapy. Thus a balance must be found between the need to treat older individuals earlier, so as to sustain immune function, and the potentially greater risk of cumulative toxicity from HAART.

The nature of AIDS-defining diseases also differs between older and younger individuals. Upon AIDS diagnosis, older adults have a higher risk of developing HIV encephalopathy or wasting syndrome and of presenting multiple AIDS-defining events than younger adults.<sup>42,53</sup> Grabar et al. have also shown that among older patients, there is a higher risk of HIV encephalopathy (HR=2.8), CMV disease (HR=5.0), and Kaposi's sarcoma (HR=3.0) compared to younger patients.<sup>51</sup>

Today, as the HIV-population ages, non-AIDS defining cancers are becoming a major concern. An increased incidence of liver, lung, anal, skin as well as hematopoietic cancers was observed, as a result of the association of other risk factors (i.e., smoking, sun, HPV infection) and the HIV-induced immune dysregulation.<sup>54</sup> This fact stresses the need to include in the follow-up of the older HIV patients, the management of their age-associated cancer risk by targeted oncological screening procedures and educational programs particularly aimed at cessation of smoking, reduction of sun exposure, and dietary protein intake.

## Conclusions
